the coarse trabeculations of the right ventricle and those that are much finer in the apical part of the left ventricle.

MORPHOLOGICALLY LEFT VENTRICLE

The left ventricle is also conveniently considered in terms of inlet, trabecular, and outlet components (Fig. 47-24), although in contrast to the right ventricle, the inlet and outlet components overlap considerably in the morphologically left ventricle. The inlet component surrounds, and is limited by, the mitral valve and its tension apparatus. The two leaflets of the mitral valve, supported by two prominent papillary muscle groups and their

FIGURE 47-25 ■ The heart has been opened through the left atrioventricular junction, and it has been spread to show the difference in structure between the aortic and mural leaflets of the mitral valve. (Copyright for the original illustration from which this figure was prepared belongs to Benson R. Wilcox, Andrew C. Cook, and Robert H. Anderson.)

commissural cords and closing along a solitary zone of apposition, have widely different appearances (Fig. 47-25). The aortic leaflet is short, squat, and relatively square. This leaflet, which is in fibrous continuity with two of the leaflets of the aortic valve, is best termed the *aortic leaflet*, because it is not strictly in either an anterior or a superior position. The other leaflet is much shallower, and its junctional attachment is more extensive, being connected to the parietal part of the left atrioventricular junction; it is accurately termed the *mural leaflet*. Because the aortic leaflet of the mitral valve also forms part of the outlet of the left ventricle (Fig. 47-26), the distinction between inlet and outlet is somewhat blurred. The papillary muscles of the valve, located in anteroinferior and posterosuperior positions, are close to each other at their origin. The muscles are usually described as being posteromedial and anterolateral, but this is wrong, reflecting the penchant of previous anatomists, and others, to describe the heart as though positioned on its apex.¹ Unlike those of the tricuspid valve, the leaflets of the mitral valve have no direct septal attachments. The deep posterior diverticulum of the subaortic outflow tract displaces the aortic leaflet of the mitral valve away from the septum (see Fig. 47-26). The trabecular component of the left ventricle extends to the ventricular apex and has characteristically fine trabeculations (see Fig. 47-24).

As in the right ventricle, the apical myocardium is surprisingly thin. This feature is important to the cardiac surgeon who has reason to place catheters and electrodes in the right ventricle or drainage tubes in the left side.² Immediate perforation, or delayed rupture, can occur. The outlet component of the left ventricle supports the aortic valve. Unlike its right ventricular counterpart, it is not a complete muscular structure. The septal wall is largely composed of muscle, but the membranous septum forms part of the subaortic outflow tract. The posterior portion of the outflow tract is composed of the fibrous curtain joining the apparatus of the aortic valve to the aortic leaflet of the mitral valve (see Fig. 47-26). As with the pulmonary valve, the leaflets of the aortic valve are hinged in semilunar fashion, with the peripheral

FIGURE 47-26 ■ The specimen is opened through the left ventricular outflow tract, showing the relationship of the left bundle branch to the membranous septum and the aortic root. attachments supported at the sinotubular junction, whereas the most basal parts take origin from ventricular structures. The overall arrangement is crownlike (see Fig. 47-21), rather than forming an annulus.^{13,16}

The muscular septal surface of the outflow tract is characteristically smooth, and down this surface cascades the fanlike left bundle branch. The landmark of the descent of the left bundle branch is the membranous septum immediately beneath the zone of apposition between the right coronary and noncoronary leaflets of the aortic valve (see Fig. 47-15). The bundle descends, initially, as a relatively narrow solitary fascicle, but soon it divides into three interconnected fascicles that radiate into anterior, septal, and posterior divisions. The interconnecting radiations do not fan out to any degree until the bundle itself has descended to between one third and one half the length of the septum.

AORTA

The ascending aorta begins at the distal extremity of the three aortic sinuses, the sinotubular junction, which lies at the line of opening of the free edge of the leaflets of the aortic valve. It runs its short course passing superiorly,

obliquely to the right, and slightly forward toward the sternum. It is contained within the fibrous pericardial sac, so its surface is covered with serous pericardium. Its anterior surface abuts directly on the pulmonary trunk, which is also covered with serous pericardium. The two vessels together compose the vascular pedicle of the heart. The ascending aorta is related anterolaterally to the right atrial appendage, and posterolaterally to the right ventricular outflow tract and the pulmonary trunk. Extrapericardially, the thymus gland lies between it and the sternum. The medial wall of the right atrium, the superior caval vein, and the right pleura relate to its right side. On the left, its principal relationship is with the pulmonary trunk. Posterior to the ascending aorta is the transverse sinus of the pericardium, which separates it from the roof of the left atrium and the right pulmonary artery.

The arch of the aorta begins at the superior attachment of the pericardial reflection just proximal to the origin of the brachiocephalic artery (Fig. 47-27). It continues superiorly briefly before coursing posteriorly and to the left, crossing the lateral aspect of the distal trachea and finally terminating on the lateral aspect of the vertebral column. Here it is tethered by the parietal pleura and the arterial ligament. During its course, it gives off the brachiocephalic, the left common carotid, and the left

subclavian arteries. Bronchial arteries can arise from the arch and can be particularly troublesome if not carefully identified in the presence of aortic coarctation. The left phrenic and vagus nerves run over the anterolateral aspect of the arch just beneath the mediastinal pleura. The left recurrent laryngeal nerve takes origin from the vagus and curls superiorly around the arterial ligament before passing on to the posteromedial side of the arch. Here, the arch relates to the tracheal bifurcation and esophagus on its medial border, but also to the left main bronchus and the left pulmonary artery inferiorly.

The descending, or thoracic, aorta continues from the arch, running an initial course lateral to the vertebral bodies and reaching an anterior position at its termination. It gives off many branches to the organs of the thorax throughout its course, as well as the prominent lower nine pairs of intercostal arteries. These latter vessels are of critical concern for the cardiac surgeon. In coarctation of the aorta, they serve as primary collateral vessels to bypass the obstructed aorta, accounting for the rib notching seen in older children with this lesion. These vessels, and their branches to the chest wall, can be a source of troublesome bleeding if not properly secured when operating on such patients. In addition, the surgeon must remember that the dorsal branches of the intercostal vessels contribute a spinal branch that is important in supplying blood to the spinal cord. Because it is difficult to predict exactly from where these vital branches will arise, the surgeon must make every attempt to protect their origin from permanent occlusion. The important bronchial arteries (Fig. 47-28) also arise from the descending segment of the thoracic aorta. These vessels can become dilated in the presence of pulmonary atresia, when they serve as a source of pulmonary vascular supply.

PULMONARY TRUNK AND BRANCH PULMONARY ARTERIES

The pulmonary trunk is a short vessel, usually less than 5 cm in length in the adult (Fig. 47-29). It is completely contained within the pericardium and, like its running mate, the ascending aorta, is covered with a layer of serous pericardium except where the two vessels abut each other in the vascular pedicle. It takes origin from the most anterior aspect of the heart, lying just behind the lateral edge of the sternum and the second left intercostal space, superior and to the left of the aortic root. Initially, the pulmonary trunk overlies the aorta and the left coronary artery, but it soon moves to a side-by-side relationship with the ascending aorta. The left coronary artery turns abruptly anteriorly to lie between the left atrial appendage and the pulmonary trunk. The arterial ligament extends from the aortic arch to the very end of the pulmonary trunk as the latter divides into left and right pulmonary arteries. The left pulmonary artery courses superior to the left main-stem bronchus and laterally in front of the descending aorta before it sends branches to the hilum of the lung. The right pulmonary artery is somewhat longer than the left, having to traverse the mediastinum beneath the aortic arch, and then behind the superior caval vein, to reach the hilum of the lung. It

FIGURE 47-28 ■ This heart is positioned as it might be seen by the surgeon working through a median sternotomy. Cook, and Robert H. Anderson.)

lies in a posteroinferior position relative to the azygos vein, and is anterior to the left main bronchus. The right pulmonary artery often branches before reaching the lateral wall of the superior caval vein posterior to the transverse sinus of the pericardium. In this situation, a large upper lobar branch may be mistaken for the right pulmonary artery itself.

CORONARY ARTERIES AND VEINS

The coronary circulation is composed of the coronary arteries and veins together with the lymphatics of the heart. Because the lymphatics are of limited significance to operative anatomy, they are not discussed further. The coronary arteries are the first branches of the ascending portion of the aorta, arising from the aortic root immediately above its attachment to the heart. Normally, there are three sinuses at the aortic root, but only two coronary arteries. The sinuses can be named, therefore, according to whether they give rise to an artery, the normal arrangement being a right coronary, left coronary, and noncoronary sinus (Fig. 47-30). In this respect, the terms *right* and *left* refer to the coronary sinuses giving rise to the

right and left coronary arteries, rather than to the position of the sinuses relative to the right-left coordinates of the body. This is important because in the normal heart, the aortic root is obliquely situated, whereas in malformed hearts, the root is frequently abnormally situated. Whatever the position of the aortic root, however, the two coronary arteries, when two are present, almost always take origin from those aortic sinuses that face the sinuses of the pulmonary trunk. Because of this, it is more convenient and more accurate to term these sinuses the *left-hand-* and *right-hand-facing sinuses*, taking as the point of reference the observer standing within the nonfacing sinus and looking toward the pulmonary trunk (Fig. 47-31). This convention, introduced by the group from Leiden,¹⁷ holds true regardless of the relationships of the arterial trunks.

The coronary arteries usually arise from the aortic sinuses beneath the sinotubular junction. Deviations of origins relative to the junction are not uncommon and are considered abnormal only when they deviate by a distance greater than 1 cm. According to Bader,¹⁸ this occurs in 3.5% of hearts. The arterial opening can be deviated either toward the ventricle, so that the artery arises deep within the aortic sinus, or toward the aortic arch, so that the origin is outside the sinus. Such displacement can lead to the artery's taking an oblique course through the aortic wall, thus called an *intramural course*, which introduces the potential for luminal narrowing and

FIGURE 47-30 ■ The aorta has been removed at the level of the sinotubular junction, and the heart is photographed from above and from the right. The dissection shows the origin of the coronary arteries from the two aortic sinuses adjacent to the pulmonary trunk. Note again the circular anatomic ventriculoarterial junction between the pulmonary trunk and the right ventricular infundibular musculature (compare with Fig. 47-29). *Ant.*, Anterior; *Post.*, posterior. FIGURE 47-31 ■ From the stance of the surgeon, the two aortic sinuses supporting the coronary arteries are to the right- and left-hand sides. Conventionally, the right-hand sinus is considered sinus #1. In the normal heart, this sinus gives rise to the right coronary artery. The convention of naming the sinuses holds, regardless of the interrelationships of the arterial trunks. (Copyright for the original diagram from which this figure was prepared belongs to Benson R. Wilcox, Andrew C. Cook, and Robert H. Anderson.)

FIGURE 47-32 ■ This photograph, taken in the operating room through a median sternotomy, shows the aortic origin of the right coronary artery. RAA, Right atrial appendage. disturbances in myocardial perfusion, particularly when the deviated origin is intimately related to a valvar commissure.¹⁹

The left coronary artery almost always takes origin from a single orifice in the left-hand-facing sinus. In contrast, in about half of all hearts, there are two orifices in the right-hand-facing sinus. In such instances, the orifices are unequal in size, the larger giving rise to the main trunk of the right coronary artery, whereas the considerably smaller second orifice usually gives rise to an infundibular artery, or rarely to the artery supplying the sinus node. The coronary arteries can also arise, though rarely, from a solitary orifice, usually within the right-hand-facing sinus.

The epicardial course of the major coronary arteries follows the atrioventricular and interventricular grooves. The right coronary artery emerges from the right-hand-facing aortic sinus and immediately enters the right atrioventricular groove (Fig. 47-32). In approximately 90% of cases, this artery gives rise to the so-called posterior descending artery at the crux, the artery in reality being positioned inferiorly rather than posteriorly. In a good proportion of these cases, the artery then continues beyond the crux, and it supplies downgoing branches to the diaphragmatic surface of the left ventricle; this is called *right coronary arterial dominance* (Fig. 47-33). As the artery encircles the tricuspid orifice, it is most closely related to the origin of the valvar attachments near the takeoff of its acute marginal branch. Other important branches also take origin from this encircling segment of the artery. Immediately after its origin, the artery gives rise to downgoing infundibular branches, one of which may also arise by a separate orifice. In just over half the cases, the right coronary artery also gives rise to the artery to the sinus node. Rarely, but of major significance when present, the nodal artery can arise laterally from the right coronary artery, coursing over the lateral margin of the appendage to reach the terminal groove.²

The main stem of the left coronary artery emerges from the left-hand-facing sinus between the pulmonary

FIGURE 47-33 ■ The heart has been removed from the thorax and is positioned on its apex. The dissection shows a right dominant coronary artery. *Inf.*, Inferior; *Sup.*, superior. (Copyright for the original illustration from which this figure was prepared belongs to Benson R. Wilcox, Andrew C. Cook, and Robert H. Anderson.)

trunk and the left atrial appendage. It is a short structure, rarely extending beyond 1 cm before branching into its anterior interventricular and circumflex branches (Fig. 47-34). In some hearts, the main stem trifurcates, with an intermediate branch present between the two main branches. The intermediate branch supplies the obtuse margin of the left ventricle. The anterior interventricular artery runs within the anterior interventricular groove, giving off diagonal branches to the obtuse margin, and the important perforating branches that pass inferiorly into the septum. The first major septal perforating branch is particularly important (see Fig. 47-22), as it is at major risk when the pulmonary valve is removed for use as a homograft.²⁰ The interventricular artery then continues toward the apex, and it frequently curves under the apex onto the diaphragmatic surface of the ventricles. The circumflex branch of the left coronary artery passes backward to run in relationship with the mitral orifice. It is most closely related to the orifice when it gives rise to the inferior interventricular artery at the crux, a so-called dominant left coronary artery (Fig. 47-35). A dominant left coronary artery, however, is found in only approximately 10% of cases. When the left coronary is not dominant, the circumflex artery usually terminates by supplying downgoing branches to the pulmonary surface of the left ventricle. In approximately 45% of normal individuals, the circumflex artery also gives rise to the artery that supplies the sinus node.

Throughout much of their epicardial course, the arteries and their accompanying veins are encased in

FIGURE 47-34 ■ This dissection, with the heart positioned in anatomic position and photographed from the left side, shows the branches of the main stem of the left coronary artery. *Ant.*, Anterior; *LAA*, left atrial appendage; *Post.*, posterior; *RVOT*, right ventricular outflow tract. epicardial adipose tissue. In some hearts, the myocardium itself may form a “bridge” over segments of the artery. The role of these bridges in the development of coronary arterial disease is not clear. They can certainly be an impediment to surgeons in their effort to isolate the artery.

The coronary veins drain blood from the myocardium to the right atrium. The smaller veins—namely, the

FIGURE 47-36 ■ This specimen has been prepared by filling the coronary sinus with silastic polymer. The heart is positioned to show its diaphragmatic aspect. The coronary sinus is formed at the union of the great cardiac vein with the oblique vein of the left atrium. *Inf.*, Inferior; *Sup.*, superior. anterior and the so-called small cardiac veins—drain directly to the cavity of the atrium. They are not of surgical significance. The larger veins accompany the major arteries and are the tributaries of the coronary sinus. The great cardiac vein runs alongside the anterior interventricular (left anterior descending) artery. It encircles the mitral orifice to enter the posterior and leftward margin of the atrioventricular groove, becoming the coronary sinus as it receives the oblique vein of the left atrium (Fig. 47-36). The coronary sinus then runs within the groove, lying between the left atrial wall and the ventricular myocardium, before draining into the right atrium. At the crux, the sinus receives the middle cardiac vein, which has ascended with the inferior interventricular (posterior descending) artery, and the small cardiac vein, which has encircled the tricuspid orifice in company with the right coronary artery. Occasionally, these latter two veins drain directly to the right atrium. The orifice of the coronary sinus is guarded by the thebesian valve, which on rare occasions is imperforate. Valves are also found in the cardiac veins. That found in the great cardiac vein where it turns around the pulmonary surface is most constant and is called the *valve of Vieussens*.

SUMMARY

Myocardial and pulmonary perfusion is regulated by a complex array of influences intrinsic and extrinsic to the vasculature. Surgical decisions are generally based on the anatomy of large arteries, where the presence of obstructive lesions and vasomotor state of these vessels can affect myocardial, pulmonary, or other organ perfusion. Under normal circumstances, the microcirculation actually plays a more significant role in the regulation of blood flow. A basic understanding of vascular tone and vasomotor regulation, and the influence of various disease states, is necessary to optimize patient care. Over the past four decades, a great deal has been learned, and this has promoted the understanding of blood vessel regulation and organ perfusion in healthy and in diseased states.

The blood vessel wall is organized in three layers: the intima, media, and adventitia. The innermost, or intimal, layer is made of endothelial cells. Initially, the endothelium was thought to serve mainly as a barrier to the diffusion of macromolecules, but it is now known that the endothelium plays a pivotal role in vascular function, regulation of vascular tone, and control of local blood flow.¹ The medial layer surrounds this intimal endothelial layer, and it is composed of a variable number of smooth muscle cells. Smooth muscle cells also control vascular tone via humoral vasoactive factors, neural mediators, or local paracrine factors (Fig. 48-1). The outermost, adventitial, layer surrounds these vascular smooth muscle cells and provides structural integrity to the blood vessel, particularly larger arteries.

The classification of microvessels based on structural characteristics is rather arbitrary, and there is a lack of uniformity in the definitions of microvascular segments such as small arteries, arterioles, and venules.

Furthermore, the transition between these segments is gradual, and there is no clear demarcation between them. In general, microvessels are defined as vessels less than 300 μm in internal diameter. Capillaries are the smallest blood vessels, defined as vessels whose walls are composed of only endothelial tubes. The microvessels through which blood flows toward capillaries are arterial microvessels, and those that drain from capillaries are venous microvessels.² Arterial microvessels usually have three coats: (1) a thin tunica intima; (2) a relatively thick tunica media, composed of one to several layers of smooth muscle cells disposed circumferentially; and (3) tunica adventitia, composed of fibrous elements and fibroblasts. Venous microvessels collect the blood from capillaries and have thinner vascular walls than arterial microvessels do. Venules (50 μm in diameter) do not possess smooth muscle cell layers. Smaller venules are composed of only endothelial cells and pericytes. Venules are highly permeable and have an important role in nutrient exchange.

The regulation of myocardial perfusion depends on many intrinsic and extrinsic factors that might be affected by atherosclerotic lesions. In the coronary circulation, it has been shown that vasomotor regulation of vessels, in addition to the actual anatomy, plays an important role in coronary perfusion and operative decision making. Blood flow is also largely dependent on the resistance generated by the microcirculation. Although early studies on vasomotor regulation consisted of indirect assessments using measurements of flow and calculations of resistance, recent investigations into the properties of the intact coronary circulation have yielded much information, as have modern methods of analysis for interpretation of physiologic data.³⁻⁶

FIGURE 48-1 ■ Regulation of vascular tone by factors released from the endothelium, activated platelets and leukocytes, neuronally released factors, and circulating substances. *Ace*, Angiotensin-converting enzyme; *Ach*, acetylcholine; *ADP*, adenosine diphosphate; *Ang*, angiotensin; *cGMP*, cyclic guanosine monophosphate; *EDHF*, endothelium-derived hyperpolarizing factor; *ET*, endothelin; *5HT*, 5-hydroxytryptamine (serotonin); *NE*, norepinephrine; *NO*, nitric oxide; *NOS*, nitric oxide synthase; *PGI₂*, prostaglandin I₂.

The microcirculation possesses unique features that allow it to respond to the dynamic changes in nutrient requirements and to interact with surrounding tissue. It is important to note that although the various vascular beds in the body possess many similarities, there are also subtle differences. This chapter will discuss regulation of vascular tone, with an emphasis on coronary and pulmonary circulation, and will review the physiologic and molecular basis of recent advances in ischemic cardiac disease.

VASCULAR RESISTANCE

An understanding of vascular resistance is important, because these resistance vessels cause pressure losses and are responsible for regulation of perfusion. Initially, it was thought that the precapillary arterioles were responsible for vascular resistance, with little resistance involvement by the vessels larger than 25 to 50 μm in diameter. However, subsequent work revealed that over half of total vascular resistance is caused by vessels with diameters larger than 100 μm , even including vessels up to 300 μm .^{7,8} Contrary to previous belief, the venous circulation, under conditions of vasodilation, may account for up to 30% of vascular resistance. Figure 48-2 shows that after vasodilation with dipyridamole, larger arteries and veins assume a greater role in resistance.^{8,9} Similarly, ischemia results in a significant redistribution of vascular

FIGURE 48-2 ■ Intravascular pressures in the coronary microcirculation under basal conditions and during vasodilation with dipyridamole. The distribution of vascular resistance is not static. Instead, the size of the vessels regulating vascular tone depends on the tone of the vasculature. (Adapted from Chilian WM, Layne SM, Klausner EC, et al: Redistribution of coronary microvascular resistance produced by dipyridamole. *Am J Physiol* 256:H383–H390, 1989.)

FIGURE 48-3 ■ Transmural losses of coronary perfusion pressure in normal and hypertrophied hearts. Pressures were measured using micropuncture–servo null techniques in hearts perfused via the left main coronary artery at 100 mm Hg. (Adapted from Fujii M, Nuno DW, Lamping KG, et al: Effect of hypertension and hypertrophy on coronary microvascular pressure. *Circ Res* 71:120–126, 1992.)

resistance⁹; this reveals that the distribution of vascular resistance is dynamic and is also largely dependent on vascular tone.

The redistribution of microvascular resistance can change the myogenic tone in each microvascular segment because the luminal pressure in a certain vascular segment is determined by the systemic pressure and the upstream distribution of vascular resistance. For example, when resistance is shifted upstream by the dilation of small arterioles, the luminal pressure in the upstream microvessels decreases, resulting in myogenic dilation. Changes in the venular pressure caused by the resistance redistribution can also affect the capacity for substance exchange and lead to edema formation.

In the coronary circulation, pressure losses also occur as vessels course from the epicardium through the myocardium¹⁰; this is accentuated further in the setting of cardiac hypertrophy. Such a phenomenon is particularly relevant clinically, as it in part explains the propensity of the subendocardium to develop ischemia in hypertrophied hearts (Fig. 48-3). The hypertrophied pathologic state causes a decrease in the perfusion pressure of the subendocardium, predisposing it to ischemia and infarction.¹¹

REGULATION OF VASCULAR TONE

Intrinsic and Extrinsic Vasomotor Control

Vasomotor tone is influenced by the intrinsic properties of the vessel wall, by local innervation, and by substances from surrounding parenchymal tissue. This regulation of

vasomotor tone is critically involved in organ perfusion. Vascular responses to endogenous substances are summarized in Figure 48-4. All these factors have an especially significant role in the setting of microvascular tone.²

Based on in vitro observations, Jones and colleagues¹² found that larger arterioles are more sensitive to shear stress than myogenic factors, whereas small microvessels are more sensitive to metabolic factors. They organized arterial microvessels into three microdomains as governed by distinct forms of regulation based on vessel size: (1) small arterioles (<50 μ m), most sensitive to metabolic mediators; (2) intermediate arterioles (50 to 80 μ m), most sensitive to myogenic mechanisms; and (3) large arterioles (80 to 150 μ m), most sensitive to flow-induced dilation. Undoubtedly, there is overlap among these three components; however, this model provides a framework for understanding the regulation of microvessels.

Jones and colleagues¹² hypothesized that the longitudinal disposition of these three microdomains enables integrated adjustment of flow conductance in the face of various influences, such as increased metabolism or a reduction in perfusion pressure. For example, dilation of small arterioles by augmented metabolism produces a decrease in luminal pressure in upstream microvessels, leading to the dilation of intermediate arterioles by decreasing the myogenic tone. These microvascular dilations could also produce an increase in shear stress and result in enhanced flow-induced dilation in large arterioles. As a result, all sizes, or domains, of arterial microvessels dilate in response to the metabolic stimulation. The marked longitudinal heterogeneity of microvascular responses may be at least partly explained by this microdomain hypothesis.

Role of the Endothelium

The endothelium plays a pivotal role in vasomotor tone regulation. Many substances affect tone via endothelium-mediated mechanisms. Endothelial cells also release several substances that affect coronary

resistance, including vasodilators such as nitric oxide (NO•), prostaglandins, and vasoconstrictors including angiotensin converting enzyme endothelin, and reactive oxygen species (summarized in Fig. 48-5). As the major regulatory molecule, NO• is produced by a constitutively expressed enzyme known as *endothelial nitric oxide synthase*

(eNOS or NOS-3). NO• is formed as a result of a series of electron transfers from reduced nicotinamide adenine dinucleotide phosphate (i.e., NADPH) to flavin adenine dinucleotide (FAD) and flavin mononucleotide (FMN) on the reductase domain, and electron transfer to a prosthetic heme group in the oxygenase domain. When heme reduction occurs, arginine is catalyzed to citrulline and NO•. The NO• formed diffuses to underlying vascular smooth muscle, where its actions include stimulation of soluble guanylate cyclase, increasing the level of cyclic guanosine monophosphate (cGMP) and prompting vasodilation via activation of cGMP-dependent protein kinase.¹³ Although binding of calcium and calmodulin is a prerequisite for activity of eNOS, other events, such as phosphorylation,¹⁴ membrane binding,¹⁵ binding of eNOS with heat-shock protein 90, and association with the integral membrane protein caveolin¹⁶ can also modulate NOS activity. In addition, NO• can undergo reactions with thiol-containing compounds to form biologically active nitroso molecules.¹⁷

Although eNOS is expressed constitutively, it undergoes important gene expression regulation by factors such as shear stress, endothelial cell growth, hypoxia, exposure to oxidized low-density lipoprotein, and

exposure to cytokines.¹⁸⁻²⁰ In the coronary circulation, the release of NO• confers a state of basal vasodilation; therefore, administration of NO• synthase antagonists increases resting coronary resistance. However, when substances such as acetylcholine and bradykinin are administered, coronary microvessels of all sizes dilate, resulting in decreased coronary resistance. Endothelial NO• production is affected by a variety of mechanisms in many disease states. The signal transduction pathways through which NO• acts are summarized in Figure 48-6. It is likely that the most important pathway involves activation of soluble guanylate cyclase, which catalyzes the formation of cGMP from guanine triphosphate. The cGMP serves as an allosteric regulator of the enzyme cGMP-dependent protein kinase, which phosphorylates contractile proteins and ion channels, decreasing intracellular calcium and the sensitivity of contractile proteins to intracellular calcium. The binding of NO• to cytochrome oxidase in the mitochondria alters oxygen consumption and in turn can affect oxygen demand. Similarly, receptors for atrial natriuretic peptide and brain natriuretic peptide are also the particulate forms of guanylate cyclases, and these signal vasodilation via similar pathways. NO• is also released in response to sodium nitroprusside and organic nitrates.

FIGURE 48-6 ■ Signal transduction pathways for the vascular responses to agonists. Although $\text{NO}^\bullet$ is the major regulator of vascular tone, there are other factors that modulate endothelium-dependent vascular tone in coronary, pulmonary, and peripheral circulations. Endothelium-derived hyperpolarizing factor (EDHF) is an example. The endothelium-dependent hyperpolarization of vascular smooth muscle is mediated by the opening of a calcium-dependent potassium channel, leading to K^+ exit from the cell. When the vascular smooth muscle is hyperpolarized, voltage-sensitive calcium channels are closed, leading to a reduction in intracellular calcium. The role of the various EDHFs probably varies depending on the vessel size, the species, and the vascular bed under consideration. It is likely that several EDHFs exist, but current evidence suggests that hydrogen peroxide and epoxyeicosatrienoic acid, a cytochrome p450 metabolite of arachidonic acid, play major roles. Hydrogen peroxide is formed by the mitochondria in response to shear stress and acetylcholine. The hydrogen peroxide not only opens large conductance potassium channels; it also activates protein kinase G, causing oxidation and dimerization.²¹ Prostaglandin synthesis by the endothelium also modulates tone in the microcirculation. The predominant prostaglandin produced by endothelial cells is prostacyclin. There is substantial interaction between $\text{NO}^\bullet$, EDHF, and prostacyclin. A major stimulus for release of these factors is shear stress, or the tangential force of fluid as it flows over the endothelium, resulting in flow-dependent vasodilation. Interestingly, the importance of $\text{NO}^\bullet$ seems to decline and the role of the EDHF increases as blood vessels decrease in size. In addition, the production of EDHF may increase when $\text{NO}^\bullet$ is low. The interaction

of endothelial cells with vascular smooth muscle cells and the intermediates involved is outlined in Figure 48-7.

Role of Metabolism and Autoregulation

The ability of a vascular bed to adjust its tone to maintain a constant flow during changes in perfusion pressure is termed autoregulation.²² This process is most effective in the coronary circulation when pressure is between 40 and 160 mm Hg. The subendocardium and subepicardium differ in the range of pressures over which autoregulation can be observed. In the subendocardium flow begins to decrease at pressures of less than 60 to 70 mm Hg, whereas in the subepicardium these decreases in flow occur at significantly lower pressures.²³ Clinically, systemic arterial hypertension affects the range over which autoregulation occurs in the subendocardium, such that flow begins to decline at even higher pressures. Such a change in subendocardial perfusion pressure in the setting of hypertrophic myocardium increases the likelihood of subendocardial ischemia. Patients with systemic hypertension may have an increased lower limit of autoregulation and may be more likely to suffer brain ischemia during surgery, or other times, even at pressures sufficient to sustain adequate perfusion in patients with normal blood pressure.

The predominant changes in vasomotor tone, concerning both autoregulation and metabolic vascular regulation, occur in vessels smaller than 100 μm in diameter. The rate of oxygen consumption in the myocardium is closely related to myocardial perfusion via coronary microvascular tone. The ability of the myocardium to

FIGURE 48-7 ■ Role of the increase in cytosolic calcium concentration in the release of endothelium-derived relaxing factors (EDRF). Endothelial receptor activation induces an influx of calcium into the cytoplasm of the endothelial cell. After interaction with calmodulin, NO-synthase and cyclooxygenase are activated, leading to the release of endothelium-derived hyperpolarizing factor (EDHF). NO causes relaxation by activating the formation of cyclic GMP (cGMP) from GTP. EDHF causes hyperpolarization and relaxation by opening K^+ channels. Prostacyclin (PGI_2) causes relaxation by activating adenylate cyclase (AC), which leads to the formation of cyclic AMP (cAMP). Any increase in cytosolic calcium (including that induced by the calcium ionophore A23187) causes the release of relaxing factors. When agonists activate the endothelial cells, an increase in inositol phosphate may contribute to the increase in cytoplasmic Ca^{2+} by releasing it from the sarcoplasmic reticulum (SR). (Adapted with permission from Vanhoutte PM, Boulanger CM, Vidal M, et al: Endothelium-derived mediators and the renin-angiotensin system. In Robertson JIS, Nicholls MG, editors: *The renin-angiotensin system*, London, 1993, Gower Medical.)

extract additional oxygen to meet increased demand is limited because myocardial oxygen extraction is already near its maximal threshold under resting conditions. To account for this limitation, coronary flow rises in response to increased myocardial oxygen requirements.

Flow-Induced Dilation

Flow-induced dilation is a ubiquitous phenomenon of blood vessels in various organs of animals, including humans.^{2,24,25} Flow-induced dilation plays important physiologic roles by: (1) protecting the vessel wall against friction induced injury, (2) preventing vascular steal phenomenon by dilating upstream vessels when there is focal hyperemia, (3) reducing the heterogeneity of flow distribution, and (4) buffering the pressure distribution in response to rapid pressure changes.

The mechanism by which endothelial cells sense flow has been a focus of substantial investigation. Studies by Tzima and colleagues²⁶ have defined a mechanosensory complex composed of VE cadherin, the platelet endothelial cell adhesion molecule (PECAM-1), and the vascular endothelial growth factor receptor-2 (VEGFR-2) that is critical in this process. Shear seems to stimulate PECAM-1 and VE-cadherin, which in turn transactivate VEGFR2, leading to downstream signaling events. In contrast to the myogenic response, the endothelium is required for flow-induced dilation. Regulation of flow-mediated vasodilation is controversial, and both NO• and prostaglandins

have been shown to be involved, at least in porcine coronary arterioles.^{27,28} The exact mechanism of regulation can depend on age, vessel size, and the vascular bed under consideration. A possible flow-induced arteriolar dilation mechanism is summarized in Figure 48-8.

Autoregulation is mediated by the actions of several factors such as NO•, EDHF, and adenosine. Removal of a particular factor does not prevent autoregulation, because the other factors seem to take over its function. Adenosine and hydrogen peroxide also cause hyperpolarization of vascular smooth muscle. From the work of Duncker and colleagues,²² and others, we now know that several factors work together to influence metabolic regulation and autoregulation, leading to adequate regulation of coronary vascular tone despite interruption of any particular pathway.²²

Neurohumoral Influence on Microcirculation

The coronary arterial system is densely innervated with sympathetic and parasympathetic nerves.²⁹ Neurotransmitters released from these, and a wide variety of humoral substances, significantly affect the microvascular tone. Neurohumoral factors affect coronary microvascular tone, and together with myogenic, flow-induced, and local metabolic controls, they participate in determining the coronary vascular resistance necessary for oxygen and nutrition supply to the myocardium (see Fig. 48-4).

FIGURE 48-8 ■ Possible signal transduction pathway for the flow-induced arteriolar dilation, which is mediated by mechanotransduction via actin stress fibers, and the subsequent activation of the focal adhesion kinase and endothelial nitric oxide synthase (eNOS) phosphorylation. cGMP, Cyclic guanosine monophosphate; FAK, focal adhesion kinase; GTP, guanosine triphosphate; NO, nitric oxide; sGC, soluble guanylyl cyclase. (Adapted from Komaru T, Kanatsuka H, Shirato K: Coronary microcirculation: physiology and pharmacology. *Pharmacol Ther* 86:217–261, 2000.)

The role of the autonomic sympathetic and parasympathetic nervous systems is important in regulation of coronary perfusion. In vivo, the vascular response to sympathetic stimulation is mediated by both α -adrenergic and β -adrenergic receptors. In the coronary circulation, the predominant receptor subtype is the β -adrenergic receptor.³⁰ For example, direct sympathetic nerve stimulation evokes coronary vasodilation and an increase in coronary flow. If β -adrenergic antagonists are administered, a transient vasoconstriction can be observed.³⁰ When coronary microvessels are studied in vitro, α -adrenergic stimulation has minimal contractile effects. When selective α_2 -adrenergic stimulation is applied using pharmacologic stimuli, there is rather potent vasodilation of all sizes of coronary microvessels, predominantly the result of the release of endothelium-derived NO•. β -Adrenergic stimulation produces a potent relaxation of all coronary arteries, but especially of small-resistance vessels.³⁰ In addition, β_2 -adrenergic receptor subtype predominates in vessels smaller than 10 μ m in diameter in in vitro studies, whereas a mixed β_1 - and β_2 -adrenergic receptor population controls vascular resistance in in vivo studies.³⁰ On the other hand, larger coronary vessels are regulated by a mixed β_1 - and β_2 -adrenoceptor subtype population. Activation of cholinergic receptors by either vagal stimulation or the infusion of acetylcholine produces uniform vasodilation of coronary vessels.³¹ This vasodilation is predominantly mediated by endothelium-derived NO•, although release of EDHF³² and release of prostaglandin substances may contribute.³³ The coronary flow increase by vagal stimulation could be blunted by a metabolically mediated flow decrease caused by a decrease in the heart rate and myocardial contractility.³⁴

Other neurotransmitters that act on the coronary circulation include neuropeptide Y, which is mainly released with norepinephrine as a co-transmitter from sympathetic postganglionic nerve terminals upon intense sympathetic activation.^{2,35} Intracoronary application of neuropeptide Y markedly decreases coronary flow, producing myocardial ischemia without large coronary artery constriction.^{36,37} These results point to its potent and specific constrictor effects on coronary microvessels. Substance P, a potent vasodilator whose effect is dependent on the endothelium, is contained in perivascular nerve fibers and sensory ganglia.³⁸

Intrinsic Myogenic Tone

Myogenic contraction is observed when applying luminal pressure to microvessels, which causes development of intrinsic vascular tone, as shown by elevated wall tension or a decrease in vessel diameter. The microcirculation possesses this intrinsic myogenic tone response, which also contributes to maintaining basal vascular tone and autoregulation.³⁹ Recent evidence has shown that in the microcirculation, fenestrations in the internal elastic lamina allow communications between the endothelium and vascular smooth muscle. Lowering pressure activates endothelial TRPV4 channels in this microdomain, promoting endothelial cell calcium sparklets, vascular smooth muscle hyperpolarization, and vasodilation.⁴⁰ Responses

such as these play a critical role in determining the basal tone and in maintaining the intraluminal pressure of the downstream exchange vessels within a physiologic level.^{41,42} In the myocardium, myogenic responses to increases in pressure are greater in subepicardial microvessels than in vessels from the subendocardium. In addition, myogenic tone can be reduced during inflammatory states when increased expression of inducible nitric oxide synthase (iNOS) causes altered myocardial perfusion. Increases in myogenic tone, which occur during stretch of vascular smooth muscle, are associated with an increase in inositol 1,4,5-trisphosphate, presumably because of activation of phospholipase C.^{39,43,44} In addition, the myogenic tone mediator 20-HETE produces constriction of vascular smooth muscle by promoting Ca^{2+} -activated K^+ (BK) channel inhibition. This induces depolarization and increases levels of $[\text{Ca}^{2+}]_i$. This effect is most likely caused by activation of L-type Ca^{2+} channels or the activation of protein kinase C and inhibition of the Na/K-ATPase.⁴⁵ Other mediators probably involved in the myogenic tone response include mitogen-activated protein kinases and Rho protein. The downstream mediator Rho kinase can modulate myogenic tone by regulation of the actin cytoskeleton. One potential therapeutic agent for treatment of hypertension and coronary spasm is the use of Rho kinase inhibitors. A summary of possible mechanisms of myogenic tone is shown in Figure 48-9.

Impact of Extravascular and Humoral Forces on the Microcirculation

In the setting of pathologic processes such as ischemia leading to decreased tissue compliance or increased tissue edema, extravascular forces have an especially important role. For example, collateral perfusion is particularly sensitive to changes in heart rate (more frequent extravascular compression) and ventricular diameter (stretch).^{6,46} The coronary circulation is particularly unique in that it is exposed to a large number of extravascular forces produced by contraction of adjacent myocardium and intraventricular pressures. Of relevance to the concept of extravascular forces is the idea that these might collapse coronary vessels under certain circumstances. Of note, flow through the epicardial coronary arteries halted when aortic pressure fell to levels ranging from 25 to 50 mm Hg, raising the possibility that extravascular forces might be sufficiently high to collapse vessels when intraluminal pressures declined to values below this critical value.⁴⁷ Flow in the coronary microcirculation continued even when the arterial driving pressure was minimally higher than coronary venous pressure. Based on modeling and various experimental interventions, it has been determined that the decrease of antegrade blood flow in larger upstream vessels is associated with continued forward flow in microvessels and that this is due to capacitance in the coronary circulation.⁴⁸ Kanatsuka and colleagues⁴⁹ used a floating microscope to visualize epicardial capillaries and were able to show that red cells continued to flow, even after perfusion had stopped in the more proximal vessels.⁴⁹ Using this approach, they showed that the pressure at which flow stops in the epicardial coronary

FIGURE 48-9 ■ Schematic illustrations for the possible mechanisms of (A) the myogenic constriction and (B) its compensatory mechanisms. *DG*, Diacylglycerol; *20-HETE*, 20-hydroxyeicosatetraenoic acid; *IP₃*, inositol 1,4,5-trisphosphate; *PKC*, protein kinase C; *PLA₂*, phospholipase A₂; *PLC*, phospholipase C. (Adapted from Komaru T, Kanatsuka H, Shirato K: Coronary microcirculation: physiology and pharmacology. *Pharmacol Ther* 86:217–261, 2000.)

microvessels was only a few millimeters of mercury higher than right atrial pressure.⁴⁹ In addition, when ventricular diastolic pressure is high, vessels deeper in the subendocardium might be made to collapse by pressure transmitted from the ventricular chamber. In contrast, coronary epicardial vessels do not close at any pressure. It therefore seems likely that the concept of “critical closing pressure” is not applicable to all vessels in the coronary circulation.

The response of the coronary microcirculation to humoral agents differs with vessel size and location. Endothelin-1 produces vasoconstriction when administered to the adventitial surfaces of coronary microvessels. The degree of constriction produced by endothelin-1 is inversely related to the size of the vessels. In contrast, when endothelin-1 is administered intra-arterially, vasodilation occurs, presumably via release of NO•.^{31,33} Serotonin constricts vessels less than 100 μ m in diameter, whereas it causes vasodilation of smaller arteries.⁵⁰ Vasopressin, on the other hand, produces greater constriction of microvessels less than 100 μ m in diameter than it produces in larger microvessels.^{51,52} In the larger epicardial coronary arteries, vasopressin predominantly causes vasodilation.

Role of Venules in Vascular Resistance

Control of vasomotor regulation differs between the venous and arterial microcirculations, and certain reactions to pathologic stimuli occur preferentially on one side of the capillary bed. Therefore, consideration of the venous circulation apart from the arterial circulation is needed. Venules have considerable importance under conditions of vascular dilation, such as during exercise, metabolic stress, or reperfusion after myocardial ischemia.⁹ The venous circulation can influence myocardial stiffness and relaxation properties of the heart. Veins also respond differently to agonists and neuronal stimulation compared with arteries in the same vascular bed.^{33,52} Venules are also the initiating site of neutrophil adherence and transmigration, whereas arterioles seldom manifest these initial changes in the inflammatory response.⁵³ Ischemia-reperfusion has been determined to cause endothelial dysfunction in veins but, under similar conditions, arterioles appear to be more susceptible to a reduction in endothelium-dependent relaxation than are coronary venules, despite the fact that leukocytes preferentially adhere to venular rather than to arterial endothelial cells.⁵⁴ In addition, complement fragment C5a causes

neutrophil adherence in venules but not in arterioles, suggesting that different mechanisms mediate neutrophil-endothelial adherence in the two vessel types.⁵⁵

ENDOTHELIAL FACTORS IN VASCULAR GROWTH AND RESPONSE TO INJURY

It is important to identify the role of NO• and NO•-related factors in vascular development (Fig. 48-10). Nitric oxide inhibits vascular smooth muscle proliferation via apoptosis. Animal models have shown that treatment with L-nitroarginine methyl ester, an inhibitor of NO• formation, markedly increases neointimal development after vascular injury.⁵⁶ Local transfection with the eNOS cDNA also reduces the intimal proliferation that follows balloon injury.⁵⁷ The vascular response to injury is enhanced in mice deficient in eNOS.^{58,59} Thus, NO• and cGMP-elevating agents inhibit the growth of fibroblasts and vascular smooth muscle. This effect of NO• on vascular smooth muscle growth is mediated by cGMP and can be mimicked by cGMP analogs such as atrial natriuretic factor.^{59,60}

NO• plays an important role in the process of angiogenesis, and endothelial cells do not seem to be sensitive to the growth-inhibitory effects of NO•. In fact, vascular endothelial growth factor (VEGF)-1 actions during angiogenesis are mediated by NO•. Endothelial cells in the proliferative phase have a sixfold increase in eNOS expression compared with confluent ones, and eNOS knockout mice have little VEGF activity.¹⁹ During the vascular injury response, this feed-forward condition

promotes vascular growth, because while endothelial cells are proliferating to form new blood vessels, the high levels of NO• promote tube formation. Similarly, in response to the denudation injury, proliferating endothelial cells increase NO• production during the growth period to compensate for the lack of endothelial cells in the denuded area while also decreasing platelet adhesion and vascular smooth muscle proliferation in that same area. Moreover, endothelial progenitor cells (EPCs) from the bone marrow have a role in repair of denuded vessels as well as angiogenesis. Although not completely elucidated, circulating EPCs seem to vary in quantity from one patient to the next. Common risk factors such as diabetes and hypercholesterolemia decrease these cells, whereas lipid-lowering drugs such as 3-hydroxy-3-methylglutaryl-coenzyme A (HMG-CoA) reductase inhibitors increase them.

EFFECT OF DISEASE STATES ON CORONARY CIRCULATION

Coronary microvascular homeostasis can be adversely affected in disease states by altering vascular diameter, quantity, or response to humoral factors. The contribution of the endothelium to vascular regulation is particularly vulnerable to pathologies such as atherosclerosis, hyperlipidemia, diabetes, and the aging process. This mechanism is highlighted in Figure 48-11. The mechanisms underlying these abnormal endothelium-dependent responses are most likely multifactorial. Factors responsible include abnormalities of G-protein signaling,

FIGURE 48-10 ■ Schematic representation of endothelium and vascular smooth muscle, demonstrating the multifaceted roles of nitric oxide released from the endothelium in the modulation of vascular function, structure, and the response to injury. cGMP, Cyclic guanine monophosphate; PGI₂, prostacyclin.

FIGURE 48-11 ■ Reduced production and bioreactivity of endothelium-derived nitric oxide (NO•) in the setting of atherosclerosis, diabetes, and many other pathologic conditions. Asymmetric dimethylarginine (ADMA) acts as an antagonist of L-arginine. Superoxide and other oxygen free radicals may interfere with NO• availability in conditions of increased oxidant stress. The peroxynitrite radical (OONO•) can inhibit tetrahydrobiopterin (BH₄), a cofactor for nitric oxide synthase (NOS). LOO•, Peroxyl radical.

resulting in reduced activation of eNOS in response to endothelial cell receptor activation; an alteration of levels of the critical cofactor for eNOS tetrahydrobiopterin; and an overproduction of asymmetric dimethylarginine, which acts as an antagonist for the eNOS substrate L-arginine. It has been shown that oxidative stress (via increased production of vascular superoxide O₂•⁻) is particularly increased in the presence of common risk factors. Such an increase in oxidative stress will cause a reduction in endothelium-dependent vasodilation.

It is accepted that diseases that affect endothelium-dependent vascular dilation affect the coronary microcirculation as well as the larger vessels. Endothelium-dependent vasodilation acetylcholine and bradykinin is dramatically impaired in coronary microvessels from monkeys fed a high-cholesterol diet for 18 months, and sometimes paradoxical constrictions can be observed.⁶¹ Similar findings have been made in other animal models. Subsequent studies performed using *in vivo* techniques showed that vasoconstriction caused by serotonin and ergonovine (both known to be modulated by the endothelium) is markedly enhanced in the coronary microcirculation of hypercholesterolemic monkeys.⁶² These findings are impressive because the coronary microcirculation is spared from the development of overt atherosclerosis. Therefore, in the setting of a risk factor for atherosclerosis, endothelial dysfunction occurs, leading to abnormal vascular responses. In humans with hypercholesterolemia, diminished flow responses to acetylcholine are restored by cholesterol lowering.⁶³ Similar observations have been made either in humans or in experimental models of hypertension,⁶⁴ ischemia-reperfusion,^{55,65} and diabetes.⁶⁶ It has been suggested that this endothelial dysfunction plays a role in the

development of clinical symptoms despite normal coronary anatomy.

Impaired endothelium-dependent vasodilation has also been linked to increased cardiovascular events. The loss of NO• in cardiovascular disease not only leads to a decrease in vasodilation; it also predisposes to atherosclerotic lesion formation and vascular smooth muscle proliferation. NO• also has antioxidant properties and prevents adhesion molecule expression by endothelial cells. An example of relevance to the clinical setting is the endothelial changes in the coronary microcirculation after cardioplegic arrest and cardiopulmonary bypass during cardiac surgery.⁶⁷ In this setting, endothelial dysfunction persists for some time after cardiopulmonary bypass, and it normalizes thereafter. This result has important clinical implications, because it is common for patients undergoing coronary artery bypass grafting, with seemingly complete coronary revascularization, to exhibit signs of myocardial ischemia during the hours after surgery—most likely caused by endothelial dysfunction.

Collateral vessels in the coronary circulation are particularly important in coronary disease. These allow for normal resting perfusion to a region of the myocardium that is served by an occluded vessel, albeit at a lower perfusion pressure; however, the coronary arterioles nourished by collaterals develop markedly abnormal vascular reactivity—for example, impaired endothelium-dependent vascular relaxations and enhanced constrictions to vasopressin.⁵¹ Possible mechanisms of this impaired microvascular endothelium-dependent relaxation in the collateral-dependent region can involve changes in shear stress, pulsatile flow in the collateral-dependent microvasculature, or intracellular calcium levels. Such changes can cause disturbance in microvascular tone during a disease state.¹⁸

Clinically, patients suffering from ventricular hypertrophy often complain of angina-like symptoms. Animal and human studies have demonstrated that cardiac hypertrophy causes a reduction in the maximal capacity of the coronary circulation to dilate in response to either reactive hyperemia or pharmacologic stimuli.^{5,64,68} One possible cause for this abnormal response may be a mismatch between the elevated myocardial mass and the relatively reduced coronary microcirculation. Peak flow normalized to myocardial mass may be reduced because of this relative paucity of coronary arterioles, because as the myocardium hypertrophies, the coronary resistance circulation might not increase enough to keep pace with the larger muscle mass. Another possible mechanism of impaired vasodilator responses may be explained by endothelial dysfunction, because many of the diseases associated with myocardial hypertrophy are also associated with a loss of endothelial NO• production.

In normal hearts, there is a linear relationship between the diameter of an epicardial coronary artery and the mass of myocardium perfused. Interestingly, epicardial coronary arteries do not enlarge to the same extent as the myocardium hypertrophies, so that for any diameter coronary artery, the amount of myocardium perfused is increased twofold. This phenomenon is particularly

relevant in the presence of a coronary stenosis, where a small lesion that is otherwise considered minimal becomes flow limiting in a hypertrophic state.

PULMONARY VASCULAR PHYSIOLOGY

The pulmonary vascular response has unique characteristics that distinguish it from other vascular beds. The normal pulmonary circulation is a low-pressure, low-resistance circuit with little or no resting tone. In contrast to the systemic circulation, where neural and humoral mechanisms predominate, the pulmonary circulation is under the control of both active factors that affect vascular smooth muscle tone (e.g., autonomic nerves, humoral factors, gasses), and passive factors (e.g., cardiac output, left atrial pressure, airway pressure).⁶⁹

In a normal state, unlike systemic arteries, pulmonary arteries have a much thinner smooth muscle layer, which is consistent with a low-pressure system. Small pulmonary arteries are the main effectors of pulmonary vascular resistance, such as hypoxic pulmonary vasoconstriction. In addition, the pulmonary capillary bed and the systemic capillary bed respond differently. Pulmonary veins are similar in structure to pulmonary arteries, but have less smooth muscle and may be regulated differently. Constriction of pulmonary arteries results in elevated pulmonary artery pressure, which increases the pressure on the right side of the heart, whereas constriction of pulmonary veins increases pulmonary capillary pressure, and this could result in pulmonary edema. With disease, the structure of pulmonary vessels can change significantly. With a chronic increase in pulmonary vascular pressure, there is a structural remodeling, with fibrosis, particularly in the intimal layer, and increased size of the smooth muscle layer, which results in a marked alteration in control mechanisms.⁶⁹

A unique characteristic of the pulmonary circulation is its response to hypoxia. Pulmonary arteries contract when oxygen tension is acutely decreased (Fig. 48-12), unlike systemic vessels, which dilate in response to hypoxia. This phenomenon, called *hypoxia-induced pulmonary vasoconstriction* (HPV) is an important mechanism that aids in matching ventilation with perfusion by directing blood flow from poorly ventilated regions of the lung to areas with normal or relatively high ventilation.⁷⁰ Although acute HPV benefits gas exchange and maximizes oxygenation of venous blood in the pulmonary artery, sustained HPV or chronic exposure to hypoxia is a major cause of the elevated pulmonary vascular resistance and pulmonary arterial pressure in patients with pulmonary arterial hypertension associated with hypoxic cardiopulmonary diseases.⁷¹ Chronic vasoconstriction leads to vascular remodeling, pulmonary hypertension, and possibly cor pulmonale. Patients with chronic obstructive pulmonary disease, for example, are usually hypoxemic and may fall into this category. Similarly, pulmonary vasoconstriction presents a challenge in pediatric patients with congenital heart disease, as they are particularly susceptible to developing pulmonary hypertensive crises after cardiac interventions.⁷² Pulmonary vascular resistance is often increased after lung transplantation.⁷³

FIGURE 48-12 ■ Actual tracing of isolated pulmonary artery response to hypoxia. Isolated rat pulmonary artery, supported between steel wires in a 37° C organ bath containing modified Henseleit solution and connected to a force transducer, was contracted with phenylephrine (10^{-7} M) and gassed with 95% oxygen, 5% carbon dioxide (hypoxia). The resulting tension tracing exhibits relaxation preceding a transient vascular contraction. (Adapted from Tsai BM, Wang M, Turrentine MW, et al: Hypoxic pulmonary vasoconstriction in cardiothoracic surgery: basic mechanisms to potential therapies. *Ann Thorac Surg* 78:360–368, 2004.)

Hypoxia is a potent vasoconstrictive stimulus in these patients.⁷⁴

Although the exact mechanism of HPV remains unclear, many believe that it is related to the inhibition of calcium channels in the pulmonary vascular smooth muscle that leads to contraction.⁷⁵⁻⁷⁸ This hypothesis is supported by increasing evidence that an increase in cytosolic calcium appears to be an important factor in HPV development.^{77,79} Hypoxia has also been shown to promote membrane depolarization.⁷⁹ Alternatively, HPV might also be related to the inhibition or secretion of an unknown endogenous mediator that results in vasoconstriction.⁷¹ Pulmonary venous hypertension causes pulmonary endothelial dysfunction characterized by reduced bioavailability of NO• and increased formation of vasoconstrictors such as endothelin 1 and thromboxane A₂.^{80,81} Pulmonary venous hypertension may therefore increase pulmonary vasoconstriction and remodeling and cause an increase in pulmonary vascular resistance.^{82,83} Lung vascular responses may further increase pulmonary arterial pressure in congestive heart failure and augment the risk for right ventricular failure.

Aside from oxygen, agents used as potential therapies for HPV have included inhaled NO•, prostaglandins, endothelin receptor antagonists, protein kinase C inhibitors, and potassium channel activators (Fig. 48-13). Currently, advanced therapies are more likely to include combination treatments, and often incorporate endothelin receptor antagonists or cyclic GMP phosphodiesterase-5 inhibitors.⁸⁴ Inhaled vasodilators are thought to circumvent potentially deleterious systemic side effects by acting predominantly on the pulmonary circulation (e.g., epoprostenol or the phosphodiesterase-3 inhibitor milrinone).^{85,86}

FIGURE 48-13 ■ Therapeutic strategies for blocking hypoxic pulmonary vasoconstriction. (A) Inhaled nitric oxide (NO) and (B) prostacyclin (PGI_2) activate guanylate cyclase (GC) and adenylate cyclase (AC), respectively, to cause vasodilation. (C) Protein kinase C (PKC) inhibitors prevent protein kinase C-mediated vasoconstriction. (D) Endothelin receptor (ET_A , ET_B) antagonists prevent endothelin-1 (ET-1) from binding to ET_A , thus inhibiting vasoconstriction. (E) Potassium channel activation prevents calcium-dependent vasoconstriction. ATP, Adenosine triphosphate; cAMP, adenosine 3',5'-cyclic monophosphate; cGMP, guanosine 3',5'-cyclic monophosphate; GTP, guanosine triphosphate; K_v , voltage-gated potassium channel. (Adapted from Tsai BM, Wang M, Turrentine MW, et al: Hypoxic pulmonary vasoconstriction in cardiothoracic surgery: basic mechanisms to potential therapies. *Ann Thorac Surg* 78:360–368, 2004.)

IMPROVING MYOCARDIAL PERFUSION

Despite improvement in catheter-based interventions and the use of coronary artery bypass grafting, a number of patients present with such diffuse coronary artery disease (CAD) that these interventions result in incomplete or failed revascularization. These patients have poor clinical outcomes associated with decreased survival and decreased angina free survival. We will briefly discuss alternative and theoretical approaches to improve collateral formation for patients suffering from CAD not amenable to current interventions. These therapies include growth factor therapy, gene therapy, cell therapy, and adjuvant drug treatment.

It is important to note that collateral formation resulting from the generic term *angiogenesis* actually encompasses three distinct modes of vessel formation with differential regulation and developmental processes. These modes of vessel formation include “true angiogenesis,” arteriogenesis, and vasculogenesis. True angiogenesis is the growth of vessels from pre-existing vessels; arteriogenesis is the growth of large muscular arteries from existing vessels; and vasculogenesis is de novo blood vessel formation from progenitor cells. These three entities have differential regulatory and developmental processes. Of these processes, arteriogenesis most effectively improves collateral dependent myocardial perfusion.

Angiogenesis

It has also been found that treatment of collateral-dependent vessels with angiogenic growth factors and

gene therapy may enhance endothelium-dependent relaxation, in addition to improving other aspects of cardiac performance. Several animal studies have demonstrated that therapeutic angiogenic interventions, in the setting of chronic ischemia, are associated with an improvement in myocardial perfusion and endothelium-dependent vasodilation in the area supplied by collaterals.⁸⁷⁻⁸⁹ These studies used growth factors such as VEGF, fibroblast growth factor (FGF)-1, or FGF-2 placed in the perivascular area. Possible mechanisms through which these factors act include FGF-2- and VEGF-induced release of NO , which improves collateral perfusion and decreases tissue ischemia.⁹⁰ In addition, it has been shown that during periods of chronic ischemia there occurs an upregulation of FGF-2 and VEGF receptors. This finding is consistent with results showing that after administration of growth factors, endothelium-dependent relaxation occurs in the collateral-dependent region, but not in myocardium perfused via the original vessels.⁹¹ In addition, these growth factors can stimulate the release of bone marrow-derived endothelial progenitor cells that promote collateral growth and endothelial function at the treated sites. Unfortunately, clinical trials to date have not demonstrated much benefit with growth factor and gene therapy in patients. Similarly, in clinical trials cell therapy has largely failed to enhance collateral formation to provide sufficient perfusion in the setting of myocardial ischemia. A number of clinical studies have been performed in which patients received bone marrow-derived mononuclear cells or endothelial progenitor cells by infusion several days after myocardial infarction. Other clinical trials have similarly found clinically insignificant benefits or no benefit to cell therapy.⁹² These studies demonstrate that cell therapy is safe in the short and long term. Differences in study outcomes are likely related to patient selection, comorbidities, and method of delivery.

Challenges and Future Directions

Multiple factors may explain the failure to reproduce the multiple effective preclinical trials with growth factors, genes or cell therapy on vascular regeneration. Patients with end-stage CAD often have significant comorbid conditions, including diabetes and hypercholesterolemia, resulting in aberrant vascular signaling and endothelial dysfunction.⁹³ These conditions result in hostile local environments with increased oxidative stress and increased expression of anti-angiogenic proteins.⁹⁴ Technical issues may contribute to failure in growth factor therapy, including incomplete or nonsustained drug delivery. Similarly, cell-based therapies are fraught with biological and technical failures. Issues include technical failure during injection resulting in “washout,” or “leak out” of cells from injection sites in the heart, lack of homing and incorporation of cells, and cell death.⁹⁵ Potential approaches to improve homing and survival of the cells include heat shock treatment and incorporation of bioactive matrices. Another effort to improve functionality is the coadministration of growth factors with cell-based therapy. Gene-based therapies may hold the greatest promise for improving angiogenesis and myocardial perfusion, yet are the least studied and most

poorly understood. Gene-based therapies result in overexpression of survival proteins, use of genetically engineered bone marrow cells, and embryonic stem cells.⁹⁵⁻⁹⁷

In addition, investigators have also searched for adjuvant drugs to improve regenerative therapies. Commonly prescribed drugs like statins, cyclo-oxygenase inhibitors, and metformin, as well as naturally occurring substances like resveratrol have demonstrated a number of pleiotropic effects in preclinical and clinical studies.⁹⁸⁻¹⁰⁴ The direct and indirect effects of these and other drugs on hyperglycemia, hypercholesterolemia, and oxidative stress can act synergistically with other therapies to improve collateral formation.⁹⁸⁻¹⁰⁴ Despite the overall lack of clinical efficacy to date, the future of regenerative treatments holds much promise. Improvements in treating patient comorbidities along with continued advances in understanding the basic science of angiogenesis, pharmacology, genetic engineering, and more procedure based interventions will be required to demonstrate successful clinical application of regenerative therapies.

SUMMARY

This chapter provided an overview of some of the newer concepts regarding physiologic and pathophysiologic control of vascular tone. Properties of peripheral vessels cannot be extrapolated to the coronary or pulmonary circulation. Similarly, properties of one size or class of coronary microvasculature cannot be generalized. Certainly, the technology used in recent studies is dramatically changed from that of older ones. Although we attempted to focus on studies that directly examined the microvasculature using the newer technology (in vitro preparations or in situ observations), it was also important to present classical studies of the intact circulation performed in intact animals or isolated hearts. Newer research questions have necessitated the use of more basic techniques, including cell culture and molecular biological approaches. A more recent development has been the ability to make many in vivo hemodynamic measurements in human subjects in the catheterization laboratory, thus obviating the need and the expenses of flow studies in large animals. As the field of vascular biology grows, we will continue to validate our observations in the intact circulation of our patients and to translate this basic science to the clinical setting.

CARDIAC FUNCTION CURVES

INTEGRATIVE BIOLOGY OF THE MYOCARDIUM

The essential function of the muscles that make up the myocardium is to transfer to the arteries the volume of blood added to the ventricular chambers during diastole.¹ This transfer must occur within the narrow limits of end-diastolic pressures and must produce a flow of materials to the organs that matches the needs of the cells. The term *needs* means “matching the flow of oxygen,” which is consumed by the cells at a rate greater than all other materials, to the demand for oxygen. By supplying the tissues’ oxygen needs, the demand for all other substances in blood is met. An inevitable consequence of the work done during exercise is an increase in oxygen consumption, and with linear incremental increases in oxygen consumption there are linear incremental increases in cardiac output (CO) to match the increases in venous return (VR). The tight coupling of oxygen demand to CO and VR indicates a regulatory system that is able to sense the tissue oxygen needs, and to engage control mechanisms that adjust the CO. In this chapter, we are concerned with the role of the myocardium in the task of the cardiovascular system to couple oxygen demand to oxygen supply.

In accomplishing this task, the activity of the myocardium must vary over a wide range of short-term regulation (seconds, minutes, and hours) and of long-term regulation (days, weeks, and years). In the short term, during the course of a normal day as tissue oxygen demands and hence cardiac output changes from sleep to strong exercise, variations in activity of the myocardium occur by both intrinsic and extrinsic control mechanisms. The major intrinsic regulator is the Frank-Starling mechanism, in which the pressure developed by the

ventricle increases as the end-diastolic volume increases. Extrinsic regulators of the myocardium include the autonomic nerves of the sympathetic and parasympathetic systems, and humoral factors including catecholamines, thyroid hormone, and insulin. In long-term regulation, the activity of the myocardium is more permanently changed in response to chronic changes in oxygen demand associated with frequent bouts of chronic exercise and altered states of the pump and vascular system associated with aging and various long-standing pathologies. In this long-term regulation, the size of the cells composing the ventricular myocardium changes (i.e., hypertrophy or atrophy, without a change in cell number). The cells are remodeled by alterations in subcellular mechanisms regulating contraction and relaxation. This long-term regulation occurs physiologically with normal development of the heart from the immature to the mature myocardium, with normal physiologic aging, and with acquired or inherited pathologies that directly or indirectly affect the function of the myocardium.^{2,3} In this chapter, we focus on current concepts and theories of the cellular, subcellular, and molecular mechanisms for short-term regulation of the myocardium. These mechanisms are constrained to account for the dynamic and steady-state functional properties of the heart. Changes in flow and ventricular volumes during an episode of exercise reveal these functional properties.

CARDIAC DYNAMICS IN EXERCISE

Figure 49-1 displays changes in heart rate (HR), CO, stroke volume (SV), and ventricular volumes of a young healthy adult during a bout of exercise on a stationary bike. The measurements were made before and after administration of propranolol, a β -adrenergic blocking

FIGURE 49-1 ■ Dependence of heart rate (HR), cardiac output (CO), and left ventricular volumes on workload in a bout of exercise. The experiments were performed on a healthy young man before and after the administration of propranolol, a β -adrenergic blocking agent. EDV, End-diastolic volume; ESV, end-systolic volume; Pro, propranolol; SV, stroke volume. (Data courtesy Dr. Edward Lakatta.)

agent. Note that in the control condition, CO increased with workload, but end-diastolic volume (EDV) remained rather constant even though CO nearly tripled. SV increased and end-systolic volume (ESV) decreased. These data show that the increased VR that occurs in exercise is handled by the heart largely by increases in HR and decreases in ESV. Elevations in EDV as a mechanism to increase CO are not favorable because of the increased energy cost according to Laplace's law.¹ A decrease in ESV provides an important mechanism for matching CO to increased VR without increases in EDV. As we will show, this reduction in ESV at constant EDV can be one measure of the contractile ability of the cells of the heart—that is, the contractility or inotropic state of the heart. After blockade of adrenergic β -receptors with propranolol, there is a blunting of the ability of the sympathetic nervous system to influence the heart; however, CO still increased approximately threefold. This result demonstrates the ability of the cardiovascular

FIGURE 49-2 ■ Time dependence of left ventricular (LV) volume before and during exercise. Note the reduction in cycle time associated with the increased heart rate. The left panel depicts how the change in volume reflects a change in sarcomere length and cell length of ventricular myocytes composing the ventricular chamber. EDV, End-diastolic volume; ESV, end-systolic volume.

system to match the CO to the increased tissue oxygen needs without sympathetic nervous system control mechanisms. However, the increase in CO in the presence of propranolol did not occur without cost. One cost was that the increase in HR was reduced. With a decrease in HR and a constant CO, the SV had to be elevated ($CO = SV \times HR$). The increase in SV occurred largely because of an increase in EDV. Increases in EDV present a threat to the economy of contraction, and they can also stimulate hypertrophic signaling pathways as a result of cell stretch.^{2,3} These effects of propranolol indicate an important role of the β -receptors and the sympathetic nervous system in regulation of the ability of the heart to maintain CO with little or no change in EDV. Figure 49-2 depicts the dynamics of cardiac function with data relating time dependence of left ventricular volume before and after an episode of exercise. These data demonstrate the decrease in ESV with little change in EDV and enhanced dynamics and abbreviation of the contraction-relaxation cycle. The abbreviation of cardiac cycle time is critical for the maintenance of cardiac filling during the fast HR that occurs with exercise. Figure 49-2 also illustrates that the volume changes are associated with shortening of the cells composing the left ventricular chamber, and that the changes in cell length reflect changes in sarcomere length. Next, we discuss the molecular and cellular mechanisms responsible for maintenance of CO with elevations of VR with minimal change in EDV.

MOLECULAR CELLULAR BIOLOGY

Figure 49-3 depicts cellular structures involved in excitation, contraction, and relaxation. Tight junctions of low electrical resistance connect heart cells.^{4,5} When one cell is activated (depolarized), all cells become activated. Therefore, unlike skeletal muscle, the heart does not recruit motor units to regulate contraction. Instead, regulation is at the level of the cells themselves. There are mechanisms that permit regulation of the activity of each cell to meet varying demands on the circulation. We will therefore concentrate now on understanding overt left

FIGURE 49-3 ■ Microscopic view of a portion of a myocardial cell illustrating structures critical to excitation–contraction coupling. The T-tubule—containing channels and transporters—are shown as an invagination of the surface membrane (or sarcolemma), which contains surface α - and β -receptors for norepinephrine, epinephrine, and muscarinic receptors for acetylcholine. Also shown is the sarcoplasmic reticulum (SR), an internally enclosed network of tubules in which high concentrations of Ca^{2+} are stored in diastole. With electrical excitation of the cell, Ca^{2+} channels open and the small release of Ca^{2+} into the cytoplasm induces Ca^{2+} release from the SR through ryanodine receptors (RyR2; SR Ca^{2+} release channels). Ca^{2+} moves to the myofilaments (shown as a half-sarcomere; see Fig. 49-4) and activates contraction. Ca^{2+} is removed from the cytoplasm by an SR Ca^{2+} -activated Mg-ATPase (SERCA2a) and exchanged for Na^+ by the action of the $\text{Na}^+/\text{Ca}^{2+}$ exchanger (NCX) in the sarcolemma. Phospholamban (PLB) inhibits transport of Ca^{2+} by SERCA2a, and the inhibition is released when PLB becomes phosphorylated. ECF, Extracellular fluid.

ventricular cardiac function in terms of the properties of the cardiac myocytes. The objectives are to understand the following:

- The molecular and cellular mechanisms responsible for the changes in wall tension and ventricular volume that occur in the transition from diastole to systole
- The regulatory devices used by the heart to ensure ejection of an SV equal to the LV at optimal EDV during basal physiologic states and during exercise
- The mechanisms that ensure that dynamics of the heart beat are tuned to match the prevailing frequency (i.e., the HR)

SARCOMERE MECHANICS

Sarcomeres are the fundamental structural units responsible for the ability of myocardial cells to shorten and generate forces (Fig. 49-4, and see Fig. 49-3). Side arms of the myosin molecules (cross-bridges) that compose the thick filament are molecular motors that also hydrolyze adenosine triphosphate (ATP). Light chains on the myosin head, which are different in ventricles and atria, appear to regulate the rate of the ATP hydrolysis. A thick filament-associated protein (called myosin-binding protein C, or C-protein) may be important in regulating the radial movement of the cross-bridge. C-protein also binds to titin, a long structural protein that extends from the center of the sarcomere to the Z-disc. This interaction is of significance in cross-bridge function and in the

generation of passive tension. The reaction of the myosin cross-bridges with the actins of the thin filaments generates active cellular force, shortening, and power.^{6,7} The basic reaction cycle includes an attachment step; a movement of the lever arm of the myosin head, which impels the thin filament in each half-sarcomere to slide toward the center; and a detachment step, which completes the cycle.⁶ Figure 49-4 displays the cross-bridge in diastole (left) and at the end of the power stroke (right). The energy for these movements comes from the hydrolysis of one molecule of Mg-ATP during each cycle. In diastole, the cross-bridges contain bound Mg-ADP and inorganic phosphate (P_i), which has been generated from the splitting of Mg-ATP on the surface of the myosin head, poising it for reaction with actin. As actin sites become available, the cross-bridge attaches and enters into a catalytic cycle in which the release of P_i and Mg-ADP, together with isomerization of the cross-bridge, induces a progressive change in mechanical state of the cross-bridge, leading to thin-filament sliding. The terminal state is a strongly bound, so-called rigor cross-bridge that is free of P_i and nucleotide. Detachment requires binding of Mg-ATP, which is quickly split, without release of products, so that the cycle can begin again if actins remain accessible. Each actin–cross-bridge reaction cycle is therefore powered by the hydrolysis of Mg-ATP.

Ca^{2+} binding triggers conformational changes and movements of the thin-filament proteins troponin (Tn, a heterotrimeric protein complex) and tropomyosin (Tm) that switch on the actin–cross-bridge reaction.^{3,8} Figures 49-4 and 49-5 illustrate the steps in this process. In

FIGURE 49-4 ■ Illustration of a cardiac myocyte half-sarcomere showing a regulatory unit in diastole and systole. Microscopic view shows that the regulatory unit consists of seven actins, one tropomyosin (Tm), and one heterotrimeric troponin complex, which consists of a Ca^{2+} -binding protein (TnC), an inhibitory protein (TnI), and a Tm-binding protein (TnT). Although not shown here, the thin filament in a half-sarcomere contains approximately 30 regulatory units. The action of cross-bridges, discussed further in the text, in each half-sarcomere impels the thin filaments toward the center of the sarcomere by a reaction with actin powered by ATP hydrolysis. Cross-bridges are impeded from reacting with the thin filament by tropomyosin and troponin. Ca^{2+} binding to a regulatory lobe of troponin C releases the thin filament from this inhibition. Myosin-binding protein C (MyB-C) and myosin light chains (MLC1 and MLC2) modulate cross-bridge activity. Titin is a major structural protein responsible for passive tension.

FIGURE 49-5 ■ Molecular mechanism of thin filament activation by Ca^{2+} . In diastole, tropomyosin (Tm) and troponin (Tn) act to impede the thin filament-cross-bridge reaction by steric and allosteric effects on the actin sites that react with myosin. TnI, the inhibitory protein, binds tightly to actin through an inhibitory peptide (Ip). With Ca^{2+} binding to troponin C (TnC), a strong attraction between the Ip and C-terminal regions of Tn is promoted, resulting in movement of the Ip of TnI away from the actin-binding site, a release of TnT, and a movement of Tm, exposing regions of actin that react with myosin cross-bridges also.

diastole, Tn and Tm are situated on the thin filament in positions that hinder the actin-cross-bridge reaction. Tn and Tm are held in this position largely through the tethering action of troponin I (TnI). TnI is an inhibitory protein of the Tn complex, which binds tightly to actin through a highly basic peptide, to the C-terminal end of TnT, the Tm binding unit of Tn, and the C-terminal lobe of troponin C (TnC), the Ca^{2+} receptor protein. This inhibitory property of TnI is amplified by virtue of these multiple protein-protein interactions to immobilize the long α -helical Tm in a blocking position that encompasses many actins along the thin filament. When released into the myofilament space by mechanisms summarized later, Ca^{2+} binds to a single regulatory site on the N-terminal lobe of TnC, the Ca^{2+} receptor protein in the heterotrimeric Tn complex. Ca^{2+} binding to the C-lobe exposes a “sticky patch” of hydrophobic amino acids that promotes binding of TnC to the inhibitory peptide and C-terminal regions of TnI. This reaction releases the inhibitory peptide from actin and leads to a pivoting of the Tn complex on the thin filament, with TnT acting as a lever to move Tm from its blocking position on the thin filament. An important aspect of the transition from diastole to systole is that the reaction of cross-bridges with the thin filament can itself promote more actin-cross-bridge reactions by cooperative feedback mechanisms. It is apparent that cross-bridge binding can enhance the affinity of TnC for Ca^{2+} and move Tm farther away from the region of actin that reacts with the cross-bridges.

At this stage, it is important to understand that the number of cross-bridges reacting with the thin filaments determines the force generated by the sarcomere. An important determinant of the number of cross-bridges reacting with the thin filaments is the amount of Ca^{2+} released to the myofilaments and, thus, the relative occupation of sarcomeric TnC proteins with Ca^{2+} (in the basal state, this is about 20% to 25% of the total TnC).⁸ Other important determinants of the number of cross-bridges reacting with the thin filaments are the sarcomere length⁹ and the load (velocity of shortening).⁶ We will discuss the mechanisms by which each of these variables affects the number of cycling cross-bridges.

Molecular springs interlaced with the thin and thick filaments form elastic elements in the sarcomere that determine passive elastic properties of the cell and have a possible role in active contraction of the cells.¹⁰ A major elastic element is the giant protein titin (see Fig. 49-3), which is a long and flexible protein extending from the Z-disc to the midline of the sarcomere. As illustrated in Figure 49-3, titin has a region near the Z-disc that is coiled much like a spring. There is accumulating and solid evidence that when the sarcomere is stretched, titin elongates, giving rise to passive tension. Moreover, there is evidence that when the sarcomere shortens, the titin spring imposes a restoring force that is likely to be important in early diastole. Regions of titin in the thin filament–thick filament overlap zone also interact with myosin-binding protein C, a thick filament–associated

protein that binds to the head–neck region of myosin. Thus, the conformational changes in titin can also affect cross-bridge disposition. Although not depicted in Figure 48-3, the Z-disc of the sarcomere not only anchors the thin filaments; it also links sarcomeres in series by interactions between titin and the thin filaments. There are also lateral connections linking the sarcomere to the surface membrane. In addition to its role in force transmission, the Z-disc is emerging as a locus of communication in the cells. The Z-disc appears as a crossroad for interactions among many diverse proteins including channels, kinases, phosphatases, and cytoskeletal elements that connect to the nucleus and to a network of cytoskeletal proteins and membrane proteins at focal adhesion complexes.¹⁰

We will use Figure 49-6, which relates the circumferential shortening associated with the heartbeat to sarcomeric activity, to discuss the cellular and sarcomeric correlates of preload, afterload, and contractility. In Figure 49-6, we relate the contraction–relaxation cycle of the heart beat to events in a single sarcomere; mechanical changes that occur in the active and passive elements of the sarcomere are related to the beat of the heart. The sarcomere is depicted as a contractile element in series with a passive spring that is a lumped elastic element (collagen, titin, and cytoskeletal proteins). A load attached to the end of the sarcomere establishes the sarcomere length before activation and is termed the *preload*. The preload stretches the sarcomere to its diastolic length; the

FIGURE 49-6 ■ Relationships between ventricular states in the cardiac cycle and the mechanics of isolated muscle preparations. The cycle begins on the left at an end-systolic volume (ESV) and end-systolic (ES) sarcomere length. In the linear muscle setup, the analog of end-diastolic volume (EDV) is a weight—the preload—added before activation. The addition of the preload establishes sarcomere length. The load that the sarcomere discovers it must lift is not seen until after activation, and the afterload is supported on the platform. With activation as triggered by the action potential (AP) and measured as the electrocardiogram (ECG), force-generating cross-bridges react with actin; this develops tension isometrically until the tension developed matches the afterload. At that point, the sarcomere shortens with a velocity appropriate to the number of reacting cross-bridges to the load. This sarcomeric activity is reflected in the ventricle as an increase in wall tension, isovolumic (IsoVol) pressure development followed by opening of the aortic valve, and ejection of blood against the rising pressure in the aorta. Dashed lines represent measurements in which muscle length was held constant, or in which the aorta was clamped to produce an isovolumic beat. The peak amplitude of pressure or tension provides a measure of contractility. EDL, End-diastolic length; ESL, end-systolic length; LV, left ventricular.

correlate of the preload in the ventricle is the EDV. In the ventricle, an end-diastolic pressure (EDP) develops as the passive springs are stretched.

Figure 49-6 also illustrates the sarcomere with an attached afterload. The sarcomere does not “see” this load until after activation. The correlate of afterload in the ventricle is the aortic pressure. With cellular excitation, Ca^{2+} is released into the myofilament space, the cross-bridges in the sarcomere react with actin sites on thin filaments, and the cell develops tension, shortens, and stretches the elastic element. As tension increases, the afterload is lifted, and the muscle cell shortens. The sarcomere will shorten as long as it can develop tension equal to the afterload. As excitation wanes, the cell returns to the diastolic state, ready for another cycle. Figure 49-6 also shows records of the isotonic twitch (the load is constant) and the ventricular pressure. The correlate of cellular tension is the pressure (by Laplace’s law, where $\text{Wall tension} = \text{Pressure} \times \text{Radius of curvature} \div [2 \times \text{Wall thickness}]$), and the correlate of cellular length is the ventricular volume. In fact, the aortic pressure is increasing during ejection, and, thus, strictly speaking, afterload is not constant. This is referred to as an *auxotonic twitch*.

The concept of contractility is illuminated by repeating this sequence of events, but with the sarcomere held isometric (dashed lines in Fig. 49-6). In this case, the sarcomere cannot lift the load and develops the maximum isometric tension possible at the particular length, established by the preload and the extent of availability of thin filament sites for reaction with cross-bridges. The peak amplitude of isometric tension is a measure of contractility, one definition of which is maximum tension when the sarcomeres are neither lengthening nor shortening. The peak tension in the isometric twitch reflects in part the amount of Ca^{2+} delivered to the myofilaments, and in part the sarcomere length. As we will see, the amount of Ca^{2+} is a regulated variable in heart muscle cells; thus, peak tension or contractility in the isometric twitch could increase or decrease. In animal experiments, this measure of contractility can be determined in beating hearts as well.¹ The approach is to cross-clamp the aorta transiently, which creates resistance and therefore infinite afterload. Dashed lines in the right panel of Figure 49-6 show an isovolumic beat of the ventricle. The peak pressure in this isovolumic beat is a measure of the contractility in the same way that peak tension is a measure of contractility in the sarcomere.

How can contractility be measured in humans without the drastic invasive procedure of clamping the aorta? And how does this present definition of contractility relate to the previous indication that contractility is related to end-systolic length and thus end-systolic pressure (ESP) of the sarcomeres? The answers to both these questions are couched in terms of the pressure-volume loop of the left ventricular beat. Figure 49-7 shows the dependence of ventricular pressure on ventricular volume during cardiac cycles occurring at three different afterloads. The figure also illustrates that the cross-sectional area of the ventricles at the ESV and the EDV is associated with changes in sarcomere length of the cells. In a beat, the volume added during diastole (loading volume) stretches the sarcomeres from the ESV to establish the

FIGURE 49-7 ■ Pressure–volume (P–V) relationships of the left ventricle at varying end-diastolic volumes generated by infusion of blood or saline into the circulation. The P–V loops represent data obtained in human subjects in a resting condition. End-systolic pressure (ESP) points are shown as filled circles. These points represent a state in which the ventricle is neither lengthening nor shortening, and is developing the peak pressure (tension) at that particular ventricular volume (sarcomere length). Thus, points on the volume–ESP relationship reflect the length–tension properties of the muscle cells. The relationship between these points and a circumferential array of ventricular cells and the length of the sarcomere is schematically shown to illustrate that the P–V loop is rooted in a complex relationship between sarcomere length and ventricular geometry. See the text and Covell and Ross¹ for further discussion.

end-diastolic cell length and EDV. With electrical activation, Ca^{2+} is released into the myofilament space. The sarcomeres develop tension isometrically (isovolumic pressure development) until the cell tension produces a pressure greater than the aortic pressure (the afterload); the valve opens and blood is ejected from the ventricle. The ejection continues with shortening of the sarcomeres to a point at which the pressure developed in the ventricle no longer exceeds the afterload. At this ESP point, the valve closes with the waning of electrical activation and restoration of diastolic Ca^{2+} , and pressure falls isovolumically. The ESP is thus a point in which the sarcomeres are no longer shortening or lengthening. ESP is, in effect, a point essentially reflecting isometric tension—that is, a measure of contractility. The ESP points can be varied by varying afterload, as displayed in Figure 49-7 with the dashed pressure–volume loops. Afterload was increased in this example by rapidly increasing the loading volume through an increase in VR. As discussed later, these ESP points reflect isovolumic pressure or isometric cellular tension and are points on the sarcomere length–tension relationship. A line connecting these points represents a constant state of contractility. The pressure or tension is different at each of the points because the muscle and sarcomere length has changed, not because the contractility has changed. Each beat depicted in Figure 49-7 thus occurred with essentially the same amount of Ca^{2+} released to the myofilaments. The increase in ESP with increases in ventricular volume is the essence of Starling’s

law of the heart, also known as the *Frank-Starling relationship*.^{1,9}

The ESP also reflects the extent of shortening, as previously discussed. Imagine, as we will consider later, that the contractility increases. The ESP–volume relationship will shift upward and to the left, and thus at a given afterload the sarcomere will be able to shorten farther than at the previous level. Circumferential shortening will occur to a greater extent, and the SV will be increased for a given afterload. We address this concept again after describing the cellular mechanisms by which contractility can be altered.

EXCITATION–CONTRACTION COUPLING

With the realization that Ca^{2+} ions trigger and regulate the number of actin–cross-bridge reactions, it is easy to understand that switching the heart beat on and off must involve cellular mechanisms that provide and remove Ca^{2+} ions to and from troponin C. Figure 49-8 shows evidence that during a beat of the cells, there is transient increase in intracellular Ca^{2+} . Adult mammalian myocardial cells have evolved elaborate membranous structures and membrane proteins to keep Ca^{2+} away from the myofilaments during diastole, and to provide Ca^{2+} to the myofilaments during systole.^{4,11,12} The myofilaments are surrounded by a reticulum of tubular membranes, called the *sarcoplasmic reticulum* (SR). These tubules form an internally enclosed compartment that is not contiguous with the extracellular fluid and that contains a number of proteins that regulate the storage, release, and reuptake of Ca^{2+} . As illustrated in Figure 49-3, the surface membrane or sarcolemma of ventricular myocytes plunges

into the cellular interior and forms the T-tubules. These invaginations occur along the length of the cell in register with each of the sarcomeres. The T-tubules serve to bring the extracellular fluid, as well as membrane ion channels, transporters, and exchangers, into the depths of the cell interior. The T-tubules are in proximity to the terminal swellings of the SR that are the main storage depots for Ca^{2+} during diastole.

Integrated activity of proteins and protein complexes in the sarcolemma (SL), the T-tubules, the SR, and the myofilaments compose the essential elements of a process known as *excitation–contraction coupling*, whereby electrical impulses arriving at the cell are coupled to a release of Ca^{2+} and to the promotion of the actin–cross-bridge reaction.^{4,11,12} Measurements of cellular processes of membrane potential, intracellular Ca^{2+} , and tension are displayed in Figure 49-8. The triggering event is action potential depolarization of the SL and the ensuing depolarization of the sarcolemmal T-tubule. This excitatory process initiates activation of voltage-dependent, L-type Ca^{2+} channels (also known as *dihydropyridine receptors*), which are primarily clustered within the T-tubules at the sarcolemmal–SR junction. The transverse tubules of the SR contain Ca^{2+} release channels. These channels are also known as *ryanodine receptors* (RyR2, cardiac isoform) because of their ability to bind this alkaloid. Depolarization-induced influx of Ca^{2+} current (I_{Ca}) through the L-type channels contributes approximately 20% to 25% of the free Ca^{2+} in a cardiac twitch. Equally important, I_{Ca} is proposed to act locally to trigger the release of SR Ca^{2+} via the SR Ca^{2+} release channels. The release of Ca^{2+} through the RyRs contributes the remaining 75% to 80% of Ca^{2+} necessary for cardiac contraction. The process of coupling between the influx of Ca^{2+} via I_{Ca} and Ca^{2+} release from the RyR2 is known as Ca^{2+} -induced Ca^{2+} release (CICR). The gating of the RyR2 by I_{Ca} is the essence of CICR. Experiments employing fluorescent indicators that sense Ca^{2+} have revealed the activity of local clusters of RyR receptors. These experiments demonstrate elementary events known as Ca^{2+} sparks that reflect the activity of small groups of RyRs. Enhanced I_{Ca} increases localized Ca^{2+} accumulation, which increases Ca^{2+} spark frequency and produces a graded stimulation of RyR Ca^{2+} release from the SR. Release into the cytosol increases the local concentration of Ca^{2+} surrounding the myofilaments and promotes Ca^{2+} binding to TnC on the thin filaments. The reaction of Ca^{2+} with TnC triggers the protein–protein interactions that release regulatory units of the thin filament from an inhibited state (see Figs. 49-4 and 49-5). During a beat of the heart in a basal physiologic state, the amount of Ca^{2+} delivered to the myofilaments is sufficient to activate only about 20% to 25% of the regulatory units. The 75% of actin–cross-bridge reactions that remains available for increases in contractility form a molecular basis for what is commonly referred to as *cardiac reserve*.

As illustrated in Figure 49-8, the elevation in Ca^{2+} levels observed during systole is transient, with SL and SR proteins working to sequester Ca^{2+} and return it to baseline levels in the return to diastole.^{4,11,12} In the steady-state contraction–relaxation cycle, an equal efflux must match the influx of Ca^{2+} . In human hearts, this

FIGURE 49-8 ■ Schematic of action potential, intracellular transient change in Ca^{2+} , and isometric tension of a single cardiac myocyte in a basal state and during stimulation with an adrenergic agonist. The effects of adrenergic stimulation are an abbreviation of the action potential and an increase in the amplitude and dynamics of both the Ca^{2+} transient and the twitch tensions.

sequestration process involves two major cellular pumps. The majority of Ca^{2+} (70%) is re-sequestered into the SR via Ca^{2+} pumps (sarcoendoplasmic reticulum Ca^{2+} pump; SERCA2a isoform) present on the longitudinal tubules of the SR. SERCA2a is a Ca^{2+} -activated Mg-ATPase that couples Mg-ATP hydrolysis to the active transport of Ca^{2+} from the cytoplasmic space into the SR. A high-capacity, low-affinity Ca^{2+} binding protein, known as *calsequestrin*, serves as a sink for Ca^{2+} in the interior of the SR. Most of the remaining Ca^{2+} is removed from the cell via the SL $\text{Na}^+/\text{Ca}^{2+}$ exchanger operating in the inward mode (inward $\text{I}_{\text{Na}/\text{Ca}}$). Relatively small and slow processes for Ca^{2+} efflux from the cytosol include transport via a sarcolemmal Ca^{2+} pump and transport into the mitochondrial space.⁹ The proportion of Ca^{2+} flux through the $\text{Na}^+/\text{Ca}^{2+}$ exchanger and these slow processes is species dependent, with a lower proportion of Ca^{2+} handled by these mechanisms in rodents than in humans. This species difference requires consideration when applying results obtained in rodent studies to human cardiac function.⁴

MODULATION OF EXCITATION–CONTRACTION COUPLING BY PHOSPHORYLATION

The autonomic nervous system is the major regulator of the amount of Ca^{2+} delivered to the myofilaments.^{4,11,12} The myocardium has evolved an elaborate signaling cascade to link adrenergic and cholinergic neural activity as well as blood levels of neurohumors such as epinephrine and acetylcholine to modulation of cellular Ca^{2+} fluxes. As illustrated in Figure 49-9, binding of neurotransmitters, neurohumors, or pharmacologic agonists to adrenergic or cholinergic receptors triggers the cascade. GTP-binding proteins, known collectively as *G-proteins*, transduce receptor binding to an alteration of the enzyme activity of adenylyl cyclase, which is responsible for the generation of cyclic adenosine monophosphate (cAMP) from ATP. Stimulatory G-proteins (G_s) linked to adrenergic β -receptors promote the formation of cAMP, whereas inhibitory G-proteins (G_i) inhibit adenylyl cyclase and can activate phosphatases. cAMP activates protein kinase A (PKA), which phosphorylates key proteins that regulate the entry and exit of Ca^{2+} from the myofilament space. In the case of SR, the PKA substrate is phospholamban (PLB), a small proteolipid that, when dephosphorylated, inhibits the activity of SERCA2a (see Figs. 49-3 and 49-9). PLB is also a substrate for Ca^{2+} -activated calmodulin-dependent kinase (CAMK).^{4,11} This Ca^{2+} -dependent phosphorylation appears important in a “staircase” effect, in which force generated by the myocardium increases with HR. With the increased frequency, there is a higher Ca^{2+} influx because of increased amplitude and delayed inactivation of I_{Ca} . Phosphorylation of PLB by either PKA or CAMK depresses the PLB-SERCA2a interaction and releases Ca^{2+} pumping activity from inhibition; Ca^{2+} affinity of the pump increases, without changes in the maximal Ca^{2+} transport velocity. This increase in Ca^{2+} uptake increases Ca^{2+}

FIGURE 49-9 ■ Schematic representation of autonomic signal transduction and signaling in cardiac muscle cells. With binding of neurotransmitters acetylcholine (ACh) and norepinephrine (NE) to the receptors indicated, there is an activation of adenylyl cyclase (AC), elaboration of cyclic adenosine monophosphate (cAMP), and activation of protein kinase A (PKA). Levels of cAMP are also regulated by the activity of phosphodiesterases (PDE) that convert cAMP to AMP. PKA phosphorylates troponin I (TnI), phospholamban (PLB), Ca^{2+} channel subunits, and ryanodine receptors (RyR), as well as K channels (not shown). These phosphorylations elicit effects on Ca^{2+} uptake and release into the cytoplasmic space, resulting in increased contractility and dynamics of contraction and relaxation. Separate enzymes called phosphatases catalyze dephosphorylation.

loaded into the SR and induces an accelerated relaxation of the myocytes. This increase in rate of Ca^{2+} removal from the cytoplasm and myofilaments accounts in large part for the enhanced relaxation and abbreviated contraction–relaxation cycle during adrenergic stimulation. The enhanced relaxation also depends on PKA-dependent phosphorylation of TnI.^{3,8,13} The phosphorylation of TnI at PKA sites enhances Ca^{2+} release from TnC and speeds up cross-bridge cycling rate.⁸ These consequences of PLB and TnI phosphorylation are critical to the ability of the heart to tune its activity cycle to the fast heart rates during adrenergic stimulation and to accommodate the increasing VR without a significant change in EDV (see Figs. 49-1 and 49-2). A subunit in the oligomeric assembly of proteins that makes up the L-type Ca^{2+} channel of the heart is also a substrate for PKA.⁴ Phosphorylation enhances the probability that the channel will open upon depolarization, but it does not affect the unitary conductance. This increase in the trigger for Ca^{2+} release, together with the increased Ca^{2+} loading associated with PLB phosphorylation, essentially accounts for the increase in the systolic Ca^{2+} transient (see Fig. 49-8). Regulation of the release of Ca^{2+} through SR RyRs by PKA and by CAMK also provides a mechanism to control delivery of Ca^{2+} to the myofilaments and thus to control contractility by an increase in the open probability of the Ca^{2+} release channel. The amount of Ca^{2+} loaded within the SR lumen is a critical factor influencing RyR Ca^{2+} release. Increases in SR Ca^{2+} content generally stimulate the frequency and amplitude of Ca^{2+} sparks, and decreases in content reverse these trends. The duration

of the cardiac action potential is also abbreviated with adrenergic stimulation (see Fig. 49-8). This appears because of PKA-dependent phosphorylation of one form of the K channel important in determination of the duration of the action potential.¹⁴ Separate enzymes called phosphatases, which are controlled by a poorly understood regulatory pathway, catalyze dephosphorylation and restoration of the basal state.

CROSS-BRIDGES AND STROKE VOLUME

In connecting the molecular and cellular properties of the heart to cardiac output, we use the premise that the stroke volume ultimately depends on the actin–myosin interaction. Up to now, we have discussed the determinants of SV in terms of contractility, afterload, and preload. We now discuss the relationships between contractility, afterload, and preload as determinants of the number and rate of cycling of force-generating cross-bridges reacting with the thin filaments. The following equation serves to illustrate the progression of this analysis from active cross-bridges, which determine the systolic change in cell length and tension, to SV and to CO:

$$CO = HR \times SV \begin{cases} \text{(Change in LV volume and pressure)} \\ \text{(Change in cell tension and length)} \end{cases}$$

The cellular properties of length and tension are related in a highly complex manner to LV pressure and volume.¹ However, an understanding of how systolic cross-bridges determine cell tension and shortening sets the stage for understanding the geometric considerations that relate these properties to the ventricular chamber.^{1,15}

CELLULAR BIOLOGY OF CONTRACTILITY

Changes in the amount of Ca^{2+} delivered to the myofilaments, which recruit spare actin–cross-bridge reactions, can occur by the following:

- Changes in the intracellular Ca^{2+} and activity of the autonomic nervous system release neurohumors, which alter the state of phosphorylation of the regulatory proteins in the cells as described earlier.
- Changes in the chemical environment of the cells occur, such as the accumulation of metabolic wastes that occurs during a reduction in coronary flow and that results in acidosis.
- Changes in HR occur. With increases in HR, the SR fills to a greater extent with Ca^{2+} , through phosphorylations involving Ca^{2+} calmodulin-dependent kinases.
- Administration of pharmacologic agents can cause changes. Drugs that affect contractility are known as *inotropic agents*. Some agents such as dobutamine mimic adrenergic neurotransmitters, and some agents such as digitalis indirectly increase Ca^{2+} loading into the SR by inhibiting Na^+/K^+ -ATPase, reducing the Na gradient, and thus inhibiting Ca^{2+} extrusion through the Na^+/Ca^{2+} exchanger. Some inotropic agents inhibit breakdown of cAMP by an inhibition of phosphodiesterase activity, whereas other agents, known as *Ca^{2+} sensitizers*, activate the sarcomere directly.¹⁶

Figure 49-10 shows a recording of ventricular pressure and of tension developed by ventricular papillary muscles. In precise determinations of contractility, it is important that afterload and preload remain constant. Both of these constraints are met if the pressure is developed at constant LV volume or the tension is developed at constant muscle length. In this case, peak pressure or tension

FIGURE 49-10 ■ Comparison of isovolumic beats and isometric twitches at three levels of contractility. Peak amplitude of tension or pressure under these conditions provides a measure of contractility or inotropic state of the heart. Maximum rates of pressure development ($+dp/dt_{max}$) also provide a measure of contractility. Even though pressures are not developed isovolumically during normal beats, $+dp/dt_{max}$ remains a useful index of contractility. LV, Left ventricular.

would be expected to vary with the amount of Ca^{2+} delivered to the myofilaments, as would occur with variations in sympathetic nervous system stimulation, for example. Note that the rate of increase in the pressure also varies with contractility. The time derivative of the pressure trace gives the maximum rate of pressure rise ($+dp/dt$) and fall ($-dp/dt$), both of which are useful indices of contractility in the clinic, even though afterload and preload are not strictly controlled. Ejection fraction (SV/EDV) is also an index of contractility, as is the ratio of end-systolic to end-diastolic dimensions obtained from echocardiographic assessment of cardiac function.

CELLULAR BIOLOGY OF AFTERLOAD

Cardiac muscle cells lift light loads faster than heavier loads, according to a general characteristic property of striated muscle known as the force-velocity relationship.⁶ The velocity of shortening approaches a maximum value (V_{max}) as the load approaches zero, velocity is zero at the maximum load, and the cells develop maximum isometric tension under the particular conditions. As load increases between these extremes, the rate of thin-filament sliding decreases, permitting a longer time for the cross-bridges to react. By this mechanism, the number of cycling cross-bridges is matched to the load that the muscle discovers it must lift. As discussed in the context of Figure 49-6, at the isometric extreme (zero velocity), the level of Ca^{2+} activation determines maximum tension. It is also apparent that Ca^{2+} also increases V_{max} by increasing the rate that the cross-bridges enter the force-generating state. Thus, the force-velocity relationship shifts with increases or decreases in contractility.

CELLULAR BIOLOGY OF CELL LENGTH

We now explicitly relate the sarcomere length tension properties of the cardiac muscle cells to the pressure-volume relationship. Figure 49-11 displays the entire relationship between sarcomere length and the active and passive (resting) tension. Active tension rises and falls from an optimal value, whereas passive tension rises exponentially. The rise in passive tension, which would elevate diastolic LV pressure, is so steep in heart cells as to disallow filling of the ventricle to sarcomere lengths greater than 2.2 μm . In other words, during diastole, atrial pressures cannot increase enough to fill the ventricles to a volume that produces sarcomere lengths exceeding 2.2 μm . Thus, in the physiologic state, considerations of the length-tension relationships, and therefore the volume-pressure relationships of the heart, are restricted to the operating range illustrated in Figure 49-11. To measure the length-tension relationship, the muscle cells are stretched at rest to various sarcomere lengths and held isometric. The cells develop a passive tension as they are stretched. At each length, the cells are stimulated to give a measure of the total isometric tension at that particular sarcomere length. Two such lengths are illustrated in Figure 49-11. At the shorter length, there is no passive tension and maximum developed tension is

FIGURE 49-11 ■ Dependence of tension on sarcomere length. Three measurements are shown in which a linear muscle preparation (papillary muscle or trabecula) was stretched from its equilibrium length, and determinations of resting (passive) and total active force were made. Active tension is the difference between total tension and passive tension. Beyond a sarcomere length of 2.2 μm , resting tension rises to high levels that are nonphysiologic. Thus, the cells never operate beyond the working range into the *panel*. Two sarcomeres, depicted at the extreme ends of the length-tension relationship, illustrate the stretching of passive springs in titin and the change in overlap of the thin and thick filaments.

essentially zero because of the double overlap of thin filaments. At the optimal sarcomere length, active tension (the difference between total and passive tension) is at an optimum. Some resting tension exists at this sarcomere length as passive elements (notably titin) in the sarcomere and extracellular matrix are stretched. At the optimal sarcomere length of 2.2 μm , there is maximal overlap between the thick filament cross-bridges and the thin filaments.

In Figure 49-12, we show how the working range of the length-tension relationship relates to the pressure-volume relationship of the left ventricle. The basic premise is that cell and sarcomere lengths track the change in ventricular volumes, and ventricular pressure tracks changes in cell tension. Thus, one can imagine the generation of the volume-pressure relationship by an approach similar to that for generation of the length-tension relationship. In this case, although EDV is increased incrementally, EDP is measured at each volume, as is peak systolic isovolumic pressure. Figure 49-12 indicates an association of each ventricular volume with a particular sarcomere length. Important points are the following:

FIGURE 49-12 ■ Generation of systolic and diastolic pressure curves from steady-state measurements of isovolumic pressure development over a range of end-diastolic volumes. Points on the curves were generated by plotting the peak diastolic and systolic pressures at each ventricular volume in hearts with cross-clamped aortas (as in Fig. 49-6). The correlation of ventricular volume with sarcomere length and of ventricular pressure with tension emphasizes that the dependence of pressure on volume is rooted in the length–tension relationship of cardiac sarcomeres.

- Measurements of the relationship between, on the one hand, cell length and tension and, on the other, ventricular volume and isovolumic peak systolic pressure, are made at constant contractility. The basal inotropic state represents 20% to 25% of the maximal inotropic state.
- A line connecting the peak systolic pressure points determined at constant volumes is a measure of contractility. These systolic pressure points are essentially the same ESP points inscribed by variations in afterload (see Fig. 49-7). As mentioned earlier, the ESP represents a point at which the cells are neither lengthening nor shortening.
- The position of the ESP–volume relationship is a critical determinant of ESV and thus of the ability of the ventricle to eject blood.
- Figure 49-12 indicates that this position changes with an increase in contractility, which we now picture as an increase in Ca^{2+} activation of the cells that results in an increase in peak systolic pressure at a particular ventricular volume. This relationship between ventricular volume and pressure was recognized by Otto Frank and Ernest Starling over 100 years ago and is commonly referred to as the *Frank-Starling relationship* or *Starling's law of the heart*.

Despite this long-standing knowledge of Starling's law, the molecular mechanism responsible for the shape of the ESP–volume relationship remains unclear.⁹ The relationship is steeper than one would expect from simple geometric considerations of filament overlap. There is excellent evidence that this relatively steep relationship is the result of a length dependence of Ca^{2+} activation.⁹ Measurement of myofilament response to Ca^{2+} demonstrated a decrease in Ca^{2+} sensitivity as the sarcomere becomes shorter. Thus, at a constant level of systolic Ca^{2+} , we would expect the sarcomeres to be more

sensitive to Ca^{2+} as their length increases. This results in a steeper length–tension relationship that would occur with no change in Ca^{2+} sensitivity. Length-dependent changes in interfilament spacing, radial movements of cross-bridges away from the thick filament proper, and cross-bridge–dependent activation of the myofilaments have all been invoked as mechanisms for length-dependent activation.⁹

CARDIAC FUNCTION CURVES

So far, we have depicted the regulation of CO as relationships among workload, HR, and ventricular volumes (see Fig. 49-1), as relationships between time and ventricular volume changes (see Fig. 49-2), and as a relationship between ventricular volume and ventricular pressure (see Fig. 49-7). We now consider another view of regulation of cardiac output as so-called Starling curves or the Starling relationship, or simply cardiac function curves. These curves relate some measure of ventricular filling, such as EDV or EDP, to some measure of ejection, SV, or CO. Figure 49-13A depicts the transition from determinations of SV from pressure–volume loops at constant contractility and afterload to a relationship between EDV and SV. Three beats are shown at different preloads. The function curve thus provides a relationship between EDV and SV at constant afterload and contractility. Figure 49-13B indicates the shift in the cardiac function curve resulting from an elevated afterload. In this case, the pressure–volume loops show the same SV, which is achieved at an elevated EDV. Figure 49-13C indicates the shift in the cardiac function curve resulting from increased contractility. The pressure–volume loops show the same SV, which is achieved at a lower EDV and ESV. One imagines the same shift for all the preloads indicated in

FIGURE 49-13 ■ Generation of Starling cardiac function curves from pressure-volume relationships. **A**, Three beats (1, 2, 3) are shown with increases in preload at constant contractility and afterload. A plot of stroke volume (SV) at each of the end-diastolic volumes (EDV) associated with each beat generates a common form of the cardiac function curve or Starling relationship. **B**, Change in steady-state pressure-volume loop after an increase in afterload. Only beat 2 from **A** is shown for illustrative purposes, but a similar shift in the cardiac function would occur at all EDVs. **C**, Change in steady-state pressure-volume loop after an increase in contractility. Only beat 3 from **A** is shown for illustrative purposes, but a similar shift in the cardiac function would occur at all EDVs.

Figure 49-13A. With knowledge of the HR, it is possible to convert the EDV-SV relationship to a relationship between EDV and CO. Effects of increases and decreases in afterload and contractility on the relationship between EDV and CO and SV are illustrated in **Figure 49-14**.

The exact cardiac function that is operative in the heart at any particular time reflects the integrated effects of many factors. These factors include the determinants of afterload (blood pressure) and of contractility, changes in HR, levels of autonomic nervous system activity and circulating neurohumors, the intracellular and cellular chemical environment (anoxia, hypoxia, acidosis, hypercapnia, metabolites), and the presence of pharmacologic

agents that affect afterload or contractility. The EDV is determined by the flow of blood back to the heart, which in turn is determined by the total blood volume, the venous tone, resistance to flow, the pumping actions of muscle, and the intrathoracic pressure. The integrated effects of these determinants of cardiac function in the physiologic state are revealed in the exercise episode depicted in **Figure 49-1**. Pathophysiologic states can be understood in terms of a breakdown of these physiologic control mechanisms.^{16,17} For example, in heart failure, the SR Ca^{2+} load may be diminished by reduced expression of SERCA2a. There may also be alterations in myofilament response to Ca^{2+} . The ultimate effect of these

FIGURE 49-14 ■ Effect of alterations in afterload and contractility on the cardiac function curve. Each curve represents a state of constant contractility and afterload. Shifts in the cardiac function curve from a physiologic basal state (central solid line) occur with changes in afterload and contractility. CO, Cardiac output; EDV, end-diastolic volume; SV, stroke volume.

changes is a reduction in contractility, much like that simulated by β -adrenergic blockade in the data shown in Figure 49-1. With elevations in EDV, heart cells are stimulated to grow, but the growth becomes maladaptive and failure ensues as remodeling occurs. Detailed discussion of these events is beyond the scope of this chapter, but it is clear that an understanding of cardiac pathophysiology begins with an understanding of the physiology of the myocardium.^{16,17}

VENTRICULAR INTERACTION AND PERICARDIUM

Pericardium

In this chapter, we will examine the mechanics of the heart at the tissue and organ level. The chapter will focus primarily on the left ventricle (LV), but short discussions of left atrial function as it relates to LV filling and ventricular interaction will be included. First, we will review several important myocardial structural elements, an understanding of which is necessary for the understanding of function during active contraction (systole) and relaxation and filling (diastole). Next, we will review the cardiac mechanical and flow events that comprise the cardiac cycle. We will then cover diastolic and systolic function with an emphasis on pressure-volume analysis. A discussion of pump function, myocardial energy expenditure, and myocardial efficiency will follow. The finite

element method will be discussed briefly as a means to calculate regional contractility and stress. In each section, we will consider the effect that common clinical conditions such as ventricular hypertrophy and myocardial ischemia have on ventricular function. Where appropriate, we will briefly describe state of the art methods used to measure regional and global LV function.

STRUCTURE OF VENTRICULAR TISSUE

The tissue level structure of the myocardium is intimately related to systolic and diastolic function. For example, myocyte orientation determines the LV torsion

that occurs during active contraction and the subsequent untwisting that occurs during relaxation and filling. The extracellular matrix (ECM) is an important determinant of LV diastolic compliance.

Myocyte Orientation

The orientation of myofibers is complex, with variation across both the LV wall and in different LV regions. The orientation of myofibers was first quantified by Streeter and colleagues,¹ who measured myocyte orientation in tangential sections obtained across the LV wall of the dog heart and found a smooth transition in the helix angle (in the tangential plane relative to the horizontal) from the epicardium (−60 degrees) to the endocardium (+60 degrees). Myofiber orientation data collected by Streeter is seen in Figure 50-1.¹ Other studies using this histologic sampling confirmed these results in different species.

Recent advances in magnetic resonance imaging allow rapid, nondestructive assessment of muscle fibers in the entire heart. Magnetic resonance diffusion tensor imaging exploits the anisotropic diffusion of water through ordered tissues. This method has been correlated with histologically measured fiber angles² and has been used to map the fiber orientation thoroughly in the entire left ventricle of a normal rabbit, goat, sheep, and human.

FIGURE 50-1 ■ Photomicrographs of myocardial fiber orientation. (From Streeter DD Jr, Hanna WT: Engineering mechanics for successive states in canine left ventricular myocardium. II. Fiber angle and sarcomere length. *Circ Res* 33:656–664, 1973.)

Laminar Organization of Myocardium

The laminar nature of the myocardium has been appreciated since the 1800s.³ Adjacent myocytes are organized into sheets or lamina that are three to four cells thick.^{4,5} Furthermore, there are extensive cleavage planes between sheets^{4,5} that are most apparent in the midwall of the LV where the planes are radially oriented. The laminar organization of the LV has been recently championed by Torrent-Guasp,⁴ who suggested that the LV consisted of a single, folded myocardial band. Alternatively, Lagrèce and colleagues proposed a finite element–based mathematical model that represents sheet geometry.⁵ A diagram of laminar architecture of the myocardium is seen in Figure 50-2.⁵

Extracellular Matrix

The ECM is an important determinant of LV diastolic compliance. Scanning electron microscopy of the ECM demonstrates an extensive network of collagen fibers that are organized into three primary components.⁶ Briefly, the endomysium surrounds individual cells and groups of cells and the epimysium surrounds entire muscle groups.⁷ Perimysial fibers connect groups of cells. Perimysial fibers can be seen in Figure 50-2A. Of note, perimysial fibers associated with papillary muscle myocardium have a coiled shape with a potentially important role in papillary muscle strength and stiffness.⁸

THE CARDIAC CYCLE

Electromechanical Activation

The rhythmic electrical activation of the heart normally begins at the sinoatrial (SA) node. Electrical activation spreads rapidly over the atria, initiating atrial contraction. There is a delay while electrical activation moves slowly through the atrioventricular (AV) node. The electrical activation then propagates rapidly along the bundle of His, the right and left bundle branches and sub branches (Purkinje fibers) before initiating a coordinated ventricular contraction. The excitation of the ventricles results in the QRS complex of the electrocardiogram.

Cardiac Cycle

A plot of the ECG and left atrial, LV, and aortic pressures during the cardiac cycle is schematically illustrated in Figure 50-3. Depolarization and contraction of the LV raises intracavitary LV pressure. First, this causes the mitral valve to close. When LV pressure exceeds the pressure in the aorta, the aortic valve opens and pressurized blood is ejected into the aorta.

At the end of ejection, LV pressure falls below aortic pressure and the aortic valve closes. Relaxation of the myocytes is locally initiated and not directly coordinated by the conduction system. As the myocytes relax, the pressure drops in the ventricle. When LV pressure falls below the pressure in the atria, the mitral valve opens and filling begins.

FIGURE 50-2 ■ **A**, Scanning electron microscope image of a left ventricular, midanterior midwall. Tangential (TN) and transverse (TR) surfaces are shown. **B**, Schematic of cardiac microstructure. Transmural segment (1) contains layers of tightly coupled myocytes. These layers run in an approximately radial direction, and there are circumferential and tangential muscle branches between adjacent layers. Orientations of muscle fiber axes are indicated. (2), Cellular arrangement. Fine lines, components of extracellular collagen matrix. (From Legrice IJ, Hunter PJ, Smaill BH: Laminar structure of the heart: a mathematical model. *Am J Physiol* 272[5 Pt 2]:H2466–2476, 1997.)

Pressure-Volume Loop

Pressure and volume of the left ventricle are plotted as shown in [Figure 50-4](#). Active contraction (systole) begins at the bottom right corner of the loop. Contraction is isovolumic until the aortic valve opens at the top right corner and the ventricle ejects. The end of systole is the upper left hand corner of the loop. Diastole is initially isovolumic until the mitral valve opens at the bottom left corner and ventricular filling begins. Ventricular filling begins at the bottom left hand corner of the loop. Ventricular filling is broken into a period of early, rapid filling, a period of slow filling (diastasis), and filling associated with atrial systole. The end of filling is the end of diastole (bottom right corner of the loop).

DETERMINANTS OF LEFT VENTRICULAR FILLING

Pressure-Volume Analysis

Pressure-volume analysis of the cardiac cycle is a cornerstone of LV mechanics. Pressure-volume analysis of cardiac function was initially described by Otto Frank,⁹ but was initially limited by the lack of suitable methods to measure LV pressure and volume. With the development of methods including cineangiography¹⁰ and echocardiography¹¹ in 1960s that could measure ventricular volume in vivo, there was a renewed interest in the use of pressure-volume analysis to measure diastolic and systolic function.¹²

Since that time, cardiac imaging methods have advanced substantially. The imaging method most widely used for studying the heart is still echocardiography.¹³ An additional kind of data that can be obtained with echocardiography is the measurement of flow velocities (or at least the component of velocity along the line of the ultrasound beam), through the Doppler effect.¹³ Magnetic resonance imaging (MRI) with cardiac synchronization of the imaging can provide high-quality spatially registered images that can be used to calculate volumes; MRI is the current “gold standard” method for cardiac global function volume measurements.¹⁴ Computed tomography (CT) has made recent advances in imaging quality and speed, and it can also provide global functional volume measures, although it is still poorer in temporal resolution than MRI and has the additional disadvantages of involving radiation exposure and the use of potentially harmful contrast agents.¹⁴ Because CT, MRI, and three-dimensional (3D) echocardiography build collated data sets from multiple cardiac cycles, they can be used only when hemodynamics are at steady state.

The conductance catheter is best for real-time volume measurement during changes in LV preload or afterload.¹⁵ However, the inability of the conductance catheter to measure absolute ventricular volume because of parallel conductance is a limitation of the method.¹⁵

Pressure-volume loops remain similar unless loading or the strength of contraction (contractility) are changed. If preload or afterload are changed, such as by clamping the vena cava or aorta, and, while contractility remains the same, a family of curves are generated. The end-diastolic and end-systolic points subtend two lines. The

FIGURE 50-3 ■ The cardiac cycle. The time course of pressure in the pulmonary artery and right ventricle is similar to that in the aorta and left ventricle, but at a smaller scale. (Adapted from Hurst JW, Logue RB: *The Heart*, ed 2, New York, 1970, McGraw-Hill, p 76.)

end-diastolic line, referred to as the *end-diastolic pressure-volume relationship* (EDPVR) or ventricular compliance curve, is typically curvilinear. A typical EDPVR relationship is seen in [Figure 50-5A](#). The end-systolic line, referred to as the *end-systolic pressure-volume relationship* (ESPVR) or end-systolic elastance, is nearly straight. The ESPVR relationship is discussed further later.

BOX 50-1 End-Diastolic Pressure-Volume Relationship

The EDPVR is affected by:

- Myocardial (myocyte and extracellular matrix) passive stiffness
- Myocyte relaxation
- Ventricular suction
- Ventricular interaction
- Pericardium

End-Diastolic Pressure-Volume Relationship (Left Ventricular Compliance)

The EDPVR is typically described by an exponential relationship¹²:

$$P_{ED} = A + Be^{\alpha V_{ED}}, \quad (1)$$

where P is left ventricular pressure, V is left ventricular volume, ED is end-diastole, A is an offset in left ventricular pressure, and B and α are diastolic stiffness constants. Note that a shift of the EDPVR curve upward and to the left represents an increase in diastolic chamber stiffness (decrease in compliance). A shift of the curve downward or to the right means that diastolic chamber stiffness is decreased (increase in compliance).

Of note, statistical comparison of EDPVR between subjects before and after interventions is an issue. A t test is not appropriate because it fails to take colinearity into account.^{16,17} A log transform allows the use of multiple linear regression, but the offset term (A) must be removed.^{16,17}

$$\ln(P_{ED}) = \ln(B) + \alpha(V_{ED}), \quad (2)$$

where P is left ventricular pressure, V is left ventricular volume, ED is end-diastole, A is an offset in left ventricular pressure, and B and α are diastolic stiffness constants. A short list of mechanical factors that combine to determine the EDPVR is seen in [Box 50-1](#).

Myocardial Stiffness

Myocyte and ECM stiffness (discussed earlier) are determinants of global LV diastolic function. It is now appreciated that the passive stiffness of the myocyte is dependent on the giant intracellular protein titin. As discussed previously (see [Fig. 49-3](#)), the Z line or disc is the center point of the I band and the attachment point of actin (thin filament). The M line is the center point of the A band (myosin; thick filaments). Titin molecules extend from the Z line to the M line.¹⁸ Successive titin molecules are arranged head-to-head and tail-to-tail, creating a continuous protein structure that extends the entire length of the myocyte. The majority of the titin I band region is extensible and functions as a molecular spring that develops a restoring force when the cell is stretched¹⁸ or compressed.¹⁹ Titin acts as a spring that when compressed

or stretched generates a restoring force.¹⁹ A diagram showing the structure of titin is seen in Figure 50-6.¹⁹

Myocyte Relaxation

Left ventricular relaxation is a component of early diastolic filling. LV relaxation is an energy-dependent process involving the removal of Ca^{2+} from troponin-C, followed by the dissociation of actin and myosin cross bridges, thus allowing the myofibrils to relax and to return to their original end-diastolic length.²⁰ A typical LV relaxation curve is seen in Figure 50-5B.²¹

LV relaxation is classically evaluated by the exponential time constant of isovolumic relaxation (T), requiring cardiac catheterization to measure LV pressure.

$$P(t) = P_0 e^{-\frac{t}{T}}, \quad (3)$$

where $P(t)$ is left ventricular pressure as a function of time, P_0 is the pressure at the time of $dP/dt_{\min}$, t is time after $dP/dt_{\min}$, and T is the time constant of isovolumic pressure fall.²² Figure 50-5B demonstrates how relaxation pressure (Equation 3) can be subtracted from actual diastolic pressure data to obtain a corrected pressure.²¹

Left Ventricular Torsion and Recoil

The myofiber architecture described earlier (Structure of Ventricular Tissue) causes the LV to undergo torsion during systole. The magnitude of torsion is a function of myocyte contractility.²³ As myocyte contraction and torsion occurs, extracellular collagen matrix,²⁴ and intracellular titin are compressed.¹⁸ Untwisting occurs in early diastole. Forty percent of the LV untwisting occurs during isovolumic relaxation.²⁵

LV untwist continues during ventricular filling. Mitral valve opening is immediately followed by the development of a pressure gradient between the LV apex and

base,²⁶ which determines early LV filling.²⁷ The rate of untwisting is a predictor of the pressure gradient between the LV apex and base as well as the time constant of diastolic relaxation.²⁸ Finally, the rate of recoil is a preload-independent assessment of LV relaxation.²⁹

Ventricular Suction

The presence of negative intracavitary LV pressure in early diastole was shown in a series of experiments^{30,31} in which a Starr Edwards mitral prosthesis was modified to close during diastolic filling. Data from one of Yellin's experiments in which mitral valve occlusion caused a negative LV pressure (to the right of the gray bar) is seen in Figure 50-7.³¹

It is now thought that ventricular suction is caused by LV untwisting and elastic recoil of the compressed myocytes in early diastole. The concept is that end-systolic volume is lower than the diastolic equilibrium volume.³² Consequently, and depending on the time course of myocyte relaxation, the LV generates the negative intracavitary pressure described earlier. In short, ventricular suction helps to draw blood into the chamber across the mitral valve.

Echocardiographic Measures of Diastolic Function

Most clinical measurements of diastolic function focus on echocardiographic Doppler transmitral blood flow patterns. Normally, early flow (E wave) is higher than that associated with atrial contraction (A wave). Mitral flow patterns are seen in Figure 50-8.³³ Diastolic dysfunction is typically associated with a reversal of the E/A ratio.³⁴ However, the E/A ratio in dilated cardiomyopathy can range between complete A wave dominance that suggests decreased ventricular compliance and a pseudo-normalized pattern (E wave dominance).³⁵ Mitral flow patterns are difficult to interpret, however, because of

FIGURE 50-5 ■ Characterization of end-diastolic pressure-volume relationship (EDPVR) by multiple-beat (A) and relaxation-corrected single-beat (B) methods. Note that the graph in A is expanded from the complete pressure-volume loop data (insert). LV, Left ventricular. (From Jaber WA, Lam CS, Meyer DM, et al: Revisiting methods for assessing and comparing left ventricular diastolic stiffness: impact of relaxation, external forces, hypertrophy, and comparators. *Am J Physiol Heart Circ Physiol* 293[5]: H2738–2746, 2007.)

confounding factors including atrial pressure, ventricular relaxation time, and mitral regurgitation.³⁶ In addition, aging is associated with a decrease in the E/A ratio, possibly related to increasing myocardial fibrosis with age.³⁷ Abnormal mitral flow patterns are seen in Figure 50-8.³³

Atrial Contraction

The atrial contraction near the end of ventricular diastole augments the final filling of the ventricle before the next ventricular contraction.³⁸

Diastolic Dysfunction from Myocardial Ischemia

Acute coronary occlusion causes the EDPVR to shift upward and to the left.³⁹ It was initially thought that the change in EDPVR was due to an increase in myocardial passive stiffness. However, it is now thought that the change in EDPVR is secondary to increased right ventricular pressure mediated by an intact pericardium.⁴⁰ Anterior myocardial ischemia is also associated with a decrease in the pressure gradient between the LV apex and base that normally occurs during the rapid filling phase of diastole. The mechanism is thought to be a loss of myocardial contractility and LV torsion and subsequent inability to store energy that would be released during elastic recoil.²⁶ Of note, patients with DCM show abnormally low diastolic suction.⁴¹ The mechanism may be similar.

Diastolic Dysfunction from Hypertrophy

Concentric hypertrophy is hypertrophy of the LV in which the ratio of wall thickness to ventricular radius is increased.⁴² It is commonly caused by hypertension and aortic stenosis. The cause of diastolic dysfunction in concentric hypertrophy is thought to be an increase in myocardial stiffness rather than a change in myocardial relaxation or recoil.⁴³ In patients with aortic stenosis, diastolic dysfunction is found in approximately 50% of the patients with normal systolic ejection performance and in 100% of the patients with depressed function.⁴⁴

SYSTOLIC FUNCTION AND END-SYSTOLIC ELASTANCE

Cardiac Output and Cardiac Index

The simplest and most common measures of systolic function are cardiac output (CO) and ejection fraction. The difference between the volume at end diastole (ED) and end systole (ES) is the stroke volume (SV):

$$SV = V_{ED} - V_{ES}, \quad (4)$$

and the cardiac output is the stroke volume multiplied by the heart rate (HR).

$$CO = HR \times SV \quad (5)$$

To account for the differences to be expected in the values of the cardiac output for differently sized subjects, we can use the cardiac index (CI), which scales the cardiac output for body surface area:

$$CI = \frac{CO}{BSA} \quad (6)$$

Swan-Ganz Catheter

The indicator dilution technique is widely used to estimate cardiac output and thermodilution using a Swan-Ganz catheter is the most common method of indicator

FIGURE 50-6 ■ Working hypothesis of how titin generates both passive and restoring forces. *Ig*, Immunoglobulin; *PEVK*, proline, glutamate, valine, and lysine. (From Helmes M, Trombitas K, Granzier H: Titin develops restoring force in rat cardiac myocytes. *Circ Res* 79[3]:619–626, 1996.)

dilution.⁴⁵ A room temperature bolus of saline is injected into the right atrium through the proximal port of the Swan-Ganz catheter. A thermistor in the tip of the catheter measures the change in temperature as the bolus of saline is carried through the pulmonary artery.⁴⁵ Thermodilution cardiac output compares favorably with measurement of cardiac output using the Fick principle.⁴⁶

The Swan-Ganz catheter is used by many cardiac surgery units; however, there has been recent controversy over the risk benefit of the device.⁴⁷ Complications including right ventricular perforation and pulmonary artery rupture occur in 0.1% of patients.⁴⁸ A recent meta-analysis found the odds ratio to be 1.0.⁴⁹

Ejection Fraction

The ratio of the SV to the ED volume is the ejection fraction (EF):

$$EF = \frac{SV}{V_{ED}} \quad (7)$$

Both cardiac output and ejection fraction are sensitive to afterload. Specifically, the greater the afterload (resistance to flow), the lower the cardiac output and ejection fraction will be. In addition, procedures and operations

FIGURE 50-8 ■ Diagram of a proposed grading system for diastolic dysfunction based on the progression of disease patterns in patients with cardiac disease. *LAP*, Left atrial pressure; *NYHA*, New York Heart Association class; *TAU*, time constant of left ventricular relaxation (see Equation 3). (From Nishimura RA, Tajik AJ: Evaluation of diastolic filling of left ventricle in health and disease: Doppler echocardiography is the clinician's Rosetta Stone. *J Am Coll Cardiol* 30[1]:8-18, 1997.)

that alter ventricular size and material properties can cause an increase in ejection fraction that does not represent a true increase in ventricular pump function. This point has been previously made by Dickstein and colleagues⁵⁰ in regard to Batista's operation and by Wall and colleagues⁵¹ in regard to cell transplantation. It is therefore incorrect to conclude that if a surgical procedure increases ejection fraction then that pump function has improved.

End-Systolic Pressure-Volume Relationship

Several authors developed the concept of the ESPVR and suggested that it could be used as an index of global ventricular contractility.⁵²⁻⁵⁷ In principle, the measurement of ESPVR is straightforward. It requires only the acquisition of ventricular pressure-volume (PV) loops at two or more preload or afterload conditions. The end-systolic points on these PV loops are identified, and a line is drawn through them; the slope of this line is the end-systolic (peak) elastance or $E_{\max}$.⁵²⁻⁵⁷ A typical ESPVR relationship with and without catecholamine effect is shown in Figure 50-9.⁵⁷

The ESPVR is of great value because it is inherently load independent; however, it must be recognized that the ESPVR is not pump function per se because it does not take diastolic function into consideration. As with EF, this point has been previously made by Dickstein and colleagues⁵⁰ concerning the Batista operation.

$E_{\max}$ is typically described with the following equation:

$$P_{ES} = E_{ES}(V_{ES} - V_0), \quad (8)$$

where *ES* is end systole, and E_{ES} and V_0 are the slope and volume intercept of the ESPVR curve, respectively.⁵⁵ Note that a shift of the ESPVR curve upward and to the left represents an improvement in systolic chamber

FIGURE 50-9 ■ **A**, The time varying elastance ($E(t)$) concept and graph of the end-systolic pressure-volume relationship (ESPVR), with and without catecholamine effect. **B**, A graph of left ventricular pressure-volume loops of a denervated heart. *LVP*, Left ventricular pressure; *LVV*, left ventricular volume. stiffness. A shift of the curve downward or to the right means that systolic function is worse. Note that both the slope and intercept can change.¹²

Systolic Dysfunction from Myocardial Ischemia

Myocardial ischemia and infarction results in loss of contractile function of the involved myocytes. As a result, the ESPVR curve moves to the right.⁵⁸

PUMP FUNCTION

Frank-Starling Relationship

Cardiac output is regulated by intrinsic cardiac and extrinsic mechanisms. The Frank-Starling relationship is the principal intrinsic cardiac regulatory mechanism. In 1914, Patterson and Starling described the stroke volume–end diastolic pressure and the stroke volume–end diastolic pressure relationships.^{59,60} Starling's work was remarkable given that he did not possess cardiac imaging and relied on the displacement of water in a cylindrical container surrounding the heart as a measure of left ventricular volume. The stroke volume–end diastolic pressure is typically referred to as the *Frank-Starling relationship* or *Starling's law*.

The molecular determinants of the Frank-Starling relationship are discussed in Chapter 48. Briefly, the magnitude of the force generated by the myocytes is dependent on their initial length at the time of initiation of the contraction, as described by the Frank-Starling law. The general shape of the Frank-Starling relationship is seen in Figure 50-10.⁶¹ No specific mathematical relationship exists although a quadratic polynomial function has been used to approximate the relationship.⁶² Note that a shift of the Frank-Starling curve upward and to the left reflects an improvement in pump function. A shift of the curve downward and to the right implies that pump function is worse.

Recently, the stroke work–end diastolic volume relationship has been recommended by Glower and colleagues⁶¹ because of its linear nature (see Fig. 50-10).

$$SW = M_W(V_{ED} - V_W), \quad (9)$$

where M_W and V_W are the slope and intercept respectively of the preload recruitable stroke work (PRSW) relationship.⁶¹ Stroke work is defined as follows:

$$SW = \int_{ED}^{ES} P(V) dV - \int_{ES}^{ED} P(V) dV \approx P_{Max} SV, \quad (10)$$

where SW is stroke work, ED is end diastole, ES is end systole, P is left ventricular pressure, V is left ventricular volume, and SV is stroke volume. Note that two types of work must be considered. The integral from end diastole to end systole gives the work performed by the heart during ventricular ejection. Once the mitral valve opens, the vasculature then performs work on the ventricle during ventricular filling. The integral of the

pressure-volume plot under the end-diastolic pressure-volume relationship gives the work performed by the vasculature on the ventricle.

Force Frequency Relationship

The effect of contraction frequency on myocardial force generation is known as the *force frequency relationship* or as the *staircase* or *treppe phenomenon*.^{63,64} Specifically, in isolated cat papillary muscle, developed force increases substantially when contraction is increased from 20 to 200 beats/min.⁶⁵ The effect is thought to be secondary to an increase in intracellular Ca^{2+} concentration.

The force frequency relationship is operative in normal human hearts.⁶⁶ However, the effect of heart rate on E_{ES} in patients with hypertrophic cardiomyopathy⁶⁷ and on tension development in muscle strips from patients with dilated cardiomyopathy⁶⁶ is absent.

NON-STARLING REGULATION OF BLOOD PRESSURE AND CARDIAC OUTPUT

Extrinsic regulatory mechanisms of cardiac output are mediated by the autonomic nervous system and include effects on heart rate and ventricular contractility. Efferent sympathetic fibers that originate in the upper thoracic and lower cervical segments of the spinal cord synapse with postganglionic fibers in the stellate and middle cervical ganglia. Postganglionic sympathetic fibers join parasympathetic fibers to form the cardiac plexus before they course to the heart. Preganglionic parasympathetic fibers course in the vagus nerves to synapse with postganglionic fibers from cells in the epicardium of the heart.⁴⁴ Sympathetic activity increases heart rate while parasympathetic decreases heart rate. Of note, parasympathetic activity usually predominates.

Pressure and volume receptors provide input to two important heart rate regulatory mechanisms: the baroreceptor¹⁴ and Bainbridge reflexes.¹³ An increase in systemic blood pressure stimulates baroreceptors in the carotid sinus and aortic arch and increases parasympathetic tone, causing heart rate to decrease¹⁴; this is called the *baroreceptor reflex*. Conversely, an increase in circulating blood volume stimulates stretch receptors in the atria and increases sympathetic tone, causing heart rate to increase (i.e., the Bainbridge reflex).¹³ The resultant change in heart rate is the sum of the competing reflexes.

In addition, the autonomic nervous system alters atrial and ventricular contractility. Stimulation of cardiac sympathetic fibers have been shown to double LV pressure and the rate of pressure change in the isolated dog heart.⁶⁸ In contrast to the effect on heart rate, the effect of sympathetic output on contractility is stronger than parasympathetic activity.

A variety of circulating hormones effects cardiac contractility. The most obvious hormone is epinephrine, which is released from the adrenal medulla into the circulation as part of the body's fight-or-flight acute reaction to danger or other stress. Other circulating hormones that increase contractility include thyroid hormone,⁴⁰ insulin,⁴³ and glucagon.⁶⁹

(From Glover DD, Spratt JA, Snow ND, et al: Linearity of the Frank-Starling relationship in the intact heart: the concept of preload recruitable stroke work. *Circulation* 71:944–1009, 1985.)

MYOCARDIAL ENERGY EXPENDITURE AND EFFICIENCY

Determinants of Myocardial Energy Consumption

Since cardiac energy metabolism is aerobic, myocardial oxygen consumption (MVO_2) should be proportional to myocardial energy expenditure. A number of investigators have proposed models that explain the energy expenditure of the ventricle.^{70–72} Braunwald, in pioneering work that began in the 1950s, found that wall tension⁷⁰ and contractility⁷¹ were determinants of MVO_2 . The tension time index concept of Braunwald has been expanded by Weber and others to become the integral of systolic stress.⁶⁸ It should be noted that the work of Braunwald in this area is the cornerstone of our treatment of myocardial ischemia with afterload reduction and reduction of heart rate with β -blockers.

Suga and colleagues⁷³ proposed a model of myocardial energy expenditure based on pressure-volume analysis; they used an isolated heart preparation that allowed ejecting beats with a variable afterload to study the relationship between stroke work, potential energy, and myocardial oxygen consumption. Interestingly, they found a close relationship between ventricular energetics described by the pressure-volume analysis and the oxygen consumption. Specifically, they found that total oxygen consumption per beat was proportional to the sum of the potential energy (Fig. 50-11, *purple triangle*) and stroke work (see Fig. 50-11, *gold*).

$$\text{PVA} = (\text{SW} + \text{PE}) \propto \text{MVO}_2, \quad (11)$$

where *PVA* is the pressure-volume area, *SW* is the stroke work, and *PE* is potential energy.⁷³

The efficiency of ventricular function can be calculated by the ratio of external work divided by the total energy consumed per beat. Total work is equal to the total energy consumed per beat. The total energy consumed per beat is equal to the sum of the external work and the potential energy per beat. The efficiency can

FIGURE 50-11 ■ Model of myocardial energy expenditure based on pressure-volume analysis. *Gray triangle*, Potential energy. A is the end of diastole; B, the start of ejection; C, the end of systole; and D, the end of isovolumic relaxation. Please see the section on afterload and ventriculoarterial coupling for an explanation of the arterial ESPVR and E_a . *EDPVR*, End-diastolic pressure-volume relationship; *ESPVR*, end-systolic pressure-volume relationship; *PVA*, pressure-volume area; *SV*, stroke volume; *SW*, stroke work. (From Suga H: Total mechanical energy of a ventricle model and cardiac oxygen consumption. *Am J Physiol* 236[3]:H498–505, 1979.)

therefore be derived from the oxygen consumed to pump divided by the total oxygen consumed per beat.

$$\text{Efficiency} = \frac{\text{SW}}{\text{MVO}_2} \quad (12)$$

It is possible to account for all changes in SW/MVO_2 efficiency by the relative changes in E_{es} and E_a in the LV pressure-volume diagram.⁷⁴

AFTERLOAD AND VENTRICULOARTERIAL COUPLING

Optimal vascular function is essential to optimal ventricular performance. Impedance is the opposition of a system to a driving function. Maximal energy transfer of

a system is achieved when the output impedance of the source equals the input impedance of the load.

The impedance of the heart can be described by the pressure-volume relationship. The end-systolic pressure-volume relationship describes the output impedance of the heart. Sunagawa and colleagues⁷⁵ developed a formula that gives the SV for a given preload as a function of systolic ventricular properties (E_{ES} , V_0) and the arterial elastance (E_A).⁷⁵ The model included the vascular system as a modified Windkessel element, and E_A is a lumped parameter characterization of the impedance of the Windkessel element.⁷⁶ The equation is as follows:

$$SV = \frac{V_{ED} - V_0}{1 + \frac{E_A}{E_{ES}}}, \quad (13)$$

where SV is stroke volume, V is LV volume, ED is end diastole, V_0 and E_{ES} are the intercept and slope of the ESPVR relationship, respectively, and E_A is the arterial elastance.

Burkoff and Sagawa⁷⁶ extended the SV/E_A relationship (Equation 13)⁷⁵ to include SW , MVO_2 , and ventricular efficiency. The model predicted that SW would be maximum when $E_A = E_{ES}$ ($E_A/E_{ES} = 1$).⁷⁶ Of note, the afterload that resulted in the greatest efficiency was always less than that which provided the maximum SW .⁷⁶ Because of concern that the optimal E_A/E_{ES} for stroke volume and efficiency occurred at different points, De Tombe and colleagues measured stroke work in isolated hearts and found that maximal stroke work occurred at $E_A/E_{ES} = 0.80$, but that efficiency was maximal at $E_A/E_{ES} = 0.70$. However, there was a significant range of E_A/E_{ES} values where both stroke work and efficiency were greater than 90% of their maximum values (Fig. 50-12).⁷⁷ Thus, impedance matching between the LV and arterial system does seem to be important.

FIGURE 50-12 ■ Average normalized stroke work (SW) and SW per myocardial oxygen consumption (MVO_2) as a function of the curve from graphing arterial elastance (E_A) against the slope of the end-systolic pressure-volume relationship (E_{ES}). *EFF*, Efficiency. (From De Tombe PP, Jones S, Burkoff D, et al: Ventricular stroke work and efficiency both remain nearly optimal despite altered vascular loading. *Am J Physiol* 264[6 Pt 2]:H1817–1824, 1993.)

E_A/E_{ES} has subsequently been measured in patients with dilated cardiomyopathy. E_A/E_{ES} was 3.24, but was decreased to 1.86 when the patients were given dobutamine and to 1.78 with afterload reduction.⁷⁸ This study shows that impedance matching in the hypertrophied and failing heart is far from optimal and lays the ground work for afterload reduction therapy.

REGIONAL STRAIN

Strain is the normalized deformation of a body in regard to its reference configuration. For a one-dimensional rod, for example, strain is defined as:

$$\epsilon = \frac{l - l_0}{l_0}, \quad (14)$$

where ϵ is the strain, l is the deformed length, and l_0 is the initial length.

Extending one-dimensional strain to 3D requires mathematical representation as a second-order tensor defined as:

$$\epsilon = \begin{bmatrix} \epsilon_{xx} & \epsilon_{xy} & \epsilon_{xz} \\ \epsilon_{yx} & \epsilon_{yy} & \epsilon_{yz} \\ \epsilon_{zx} & \epsilon_{zy} & \epsilon_{zz} \end{bmatrix}, \quad (15)$$

where ϵ_{xx} is the normal strain in the x direction and ϵ_{xy} is shear strain on the x face in the y direction. Note that the strain tensor is symmetric with $\epsilon_{xy} = \epsilon_{yx}$ and therefore has only six independent variables. Graphic representation of normal and shear strain is illustrated in Figure 50-13.

Furthermore, the normal and shear strain values are dependent on the choice of reference frame. For instance, a reference frame in which ϵ_{xx} is oriented in the local muscle fiber direction will be different than a reference frame where ϵ_{xx} is oriented in the circumferential or hoop direction. In addition, there will always be a set of three mutually orthogonal initial directions in the tissue at each location that will remain orthogonal after motion, the “eigenvectors,” or principal directions of the deformation. One of these directions will lie along the direction of the greatest lengthening and another will lie along the direction of the smallest lengthening or greatest shortening; the strain components along these directions of the eigenvectors are called the *principal strains*. The principal strains and their directions provide a description of the deformation that is independent of the choice of reference frame.

Implanted Markers

Regional cardiac strain measurement is widely used to assess regional myocardial function. It is obvious from Equation 14 that, to measure cardiac strain, one needs to track the deformation of a specific area of tissue over time. One approach is to track implanted radiographic markers.^{79–81} A second is to use sonomicrometry to measure one-dimensional or 3D cardiac locations and strain.^{82–84} However, the invasive nature of this approach limits this approach primarily to animal research.

FIGURE 50-13 ■ Graphic representation of normal (A) and shear (B) strain.

Echocardiography

The rapid development of modern imaging techniques in recent decades, however, has made it possible to measure cardiac strain in vivo noninvasively in human subjects. Currently there are two echocardiographic methods available to measure cardiac strain. The first method is tissue Doppler imaging,⁸⁵ which uses echo Doppler to measure the velocity of myocardium in the proximal LV wall. The gradient of the velocity gives the one-dimensional rate of tissue deformation (also called *strain rate*, $e = \frac{d\epsilon}{dt}$) in the ultrasound beam direction.

Cardiac strain is then calculated by integration of the strain rate over the cardiac cycle.⁸⁵

The second echocardiographic method of strain measurement is speckle tracking echocardiography.⁸⁵ Speckles are regions of echocardiographic nonhomogeneity that appear on B-mode echocardiographic images. These regions are randomly generated artifacts caused by the reflection, refraction, and scattering of the ultrasound beam by the heart walls.⁸⁵ Speckles that remain stable can be used as markers to track cardiac motion. Typically, an image correlation method is applied offline to follow the speckles frame-by-frame. Full two-dimensional motion of the cardiac wall can be tracked and two-dimensional

cardiac strain can be subsequently calculated from these motion data. Recently, speckle tracking techniques have been extended to 3D.

Magnetic Resonance Imaging

Magnetic resonance image has several advantages as a method for noninvasive assessment of cardiac motion, including the potential to recover the full 3D motion pattern within the heart wall. Two approaches have been used to study myocardial motion with MRI. The first approach is magnetization tagging, which uses the ability of modified, noninvasive MRI techniques to create localized perturbations of the tissue magnetization (e.g., with spatial modulation of magnetization [SPAMM])⁸⁶⁻⁸⁸ noninvasively to produce MRI-visible landmarks within the heart wall. These markers move along the underlying tissue and will persist for times on the order of the tissue T_1 relaxation time (see Bernstein and colleagues⁸⁹ for references of T_1 and T_2 relaxation time), so that they can be tracked over the cardiac cycle. The second approach is the so-called displacement encoding method.⁹⁰ MRI creates images of the measured subject using magnetic fields with strong spatial gradients along three perpendicular directions. Moving objects within such magnetic field gradients cause a phase shift, which creates artifacts in the acquired image. The amount of phase-shift is known to be related linearly to the degree of motion. This property has been used in MRI noninvasively to measure in vivo blood flow velocity.⁹¹⁻⁹³ Straightforward phase shift approaches, however, are restricted by the tissue T_2 relaxation time, which is much shorter than T_1 relaxation time, and are not suitable for full cycle cardiac motion measurement.⁹⁰ The displacement encoding stimulated echo technique addressed this issue by creatively combining SPAMM and phase shift techniques together.⁹⁰ The displacement encoded phase information is stored along the direction of the static magnetic field, thus resulting in encoding duration comparable to T_1 relaxation time.

REGIONAL STRESS AND THE FINITE ELEMENT METHOD

The distributions of stress in the atrial and ventricular myocardium, valves, and fibrous structures of the heart are determined by (1) the three-dimensional geometry and tissue structure of the walls, (2) the boundary conditions imposed by the ventricular cavity and pericardial pressures and structures like the fibrous valve ring skeleton at the base of the ventricles, and (3) the three-dimensional mechanical properties of the myofibers and their collagen interconnections in the relaxed and actively contracting states. To formulate a mathematical model for predicting the distributions of wall stress in such a complex and constantly changing mechanical system is clearly difficult, but there are important reasons to attempt it. An accurate model of the mechanics of the ventricular myocardium would provide a sound basis for interpreting the complex regional changes in cardiac function that occur in pathologic conditions, such as ischemic heart disease,^{94,95} in terms of changes in the local

properties of the tissue. Knowledge of the stress distributions in the intact myocardium would also provide valuable insight into normal ventricular function because regional coronary blood flow,⁹⁶ myocardial oxygen consumption,⁷⁰ hypertrophy, and remodeling^{97,98} are all influenced by ventricular wall stress.⁹⁹

To keep the problem mathematically tractable, many workers have developed models of left ventricular mechanics using simple geometric approximations such as thin-walled spheres,¹⁰⁰ thin-walled ellipsoids,¹⁰¹⁻¹⁰⁵ thick-walled ellipsoids,^{101-104,106,107} thick-walled spheres,¹⁰⁸⁻¹¹³ thick-walled cylinders,^{96,114-121} solids of revolution,¹²² and noncircular cylinders.¹²³

The most common thin walled model is Laplace's law:

$$P = \frac{T_1}{r_1} + \frac{T_2}{r_2}, \quad (16)$$

where P is intracavitary pressure, r_1 and r_2 are the greatest and least (principal) radii of curvature of the membrane, and T_1 and T_2 are the tensions in the membrane along the corresponding directions.¹²⁴ Of note, the Laplace stress law assumes a thin-walled sphere (i.e., the ratio of wall thickness to radius is small); therefore, tension is calculated, not stress.

Such approximations generally neglect the anisotropy of the material properties of the heart wall. In addition, they generally neglect the presence of significant residual stresses in the wall even in the absence of pressure differences (the unloaded state), as manifested experimentally by the springing open of an incision into the heart wall, even in the absence of contraction or pressurized blood within the chamber.^{122,125}

Despite those limitations, stress predicted with Laplace's law is accurate in normal and globally deformed LV.¹²⁶ However, Laplace's law is not accurate in the LV after myocardial infarction (MI). For instance, Zhang and colleagues¹²⁷ found pronounced differences between modified Laplace and the finite element method in the endocardium and epicardium of the infarct border zone (BZ).¹²⁷

Formulas that are more sophisticated try to take the finite thickness of the wall into explicit account. One of the most common is the following equation developed by Janz:

$$\bar{\sigma}_{\theta\alpha} = P \frac{\Delta A_C}{\Delta A_W}, \quad (17)$$

where $\bar{\sigma}_{\theta\alpha}$ is average circumferential stress, A_C is the area of the cavity, and A_W is the area of the wall (Fig. 50-14).¹²²

Finite Element Method

As early as 1906, researchers first began suggesting the solution of continuum mechanics problems by modeling the body with a lattice of elastic bars and using frame analysis methods.¹²⁸ In 1941, Courant recognized piecewise polynomial interpolation over triangular subregions as a Rayleigh-Ritz solution of a variational problem. Neither approach was practical because there were no computers at the time, and Courant's work was

FIGURE 50-14 ■ Estimation of local myocardial stress using geometric approximations. A_C , Area of the cavity; A_W , area of the wall; r , circumferential radius of curvature at the cavity surface; R , meridional radius of curvature at the cavity surface; t , wall thickness. (From Janz RF: Estimation of local myocardial stress. *Am J Physiol* 242[5]:H875–881, 1982.)

largely forgotten until engineers had independently developed it. By 1953, structural engineers were solving matrix stiffness equations with digital computers. The widespread use of finite element methods in engineering began with the classic papers by Turner and colleagues¹²⁹ and Argyris and Kelsey.¹³⁰ The term *finite element* was coined in 1960, and the method began to be recognized as mathematically rigorous by 1963.

Many finite element models of ventricular mechanics have been proposed, although most of them did not include the nonlinear kinematic terms associated with large deformations because iterative solution of the nonlinear governing equations at each load step is required. The importance of adopting nonlinear finite deformation theory for the analysis was demonstrated by Janz and colleagues.¹³¹

A few finite element modeling studies of the left ventricle have validated stress calculations by showing good agreement with myocardial strain measured with implanted markers.^{107,120,125,132} However, this technique is invasive and is limited to few simultaneous LV locations (usually only two). With advancements in MRI, myocardial strain can be quantified noninvasively throughout the LV with tagged MRI.^{133,134} In a pioneering study, Moulton

and colleagues¹³⁵ used tagged MRI to determine isotropic, diastolic material properties in a two-dimensional finite element analysis of beating canine hearts. Using a more realistic material law, Okamoto and colleagues¹³⁶ determine anisotropic myocardial material properties in a three-dimensional finite element model using tagged MRI. However, the experimental preparation and loading conditions were not physiologic, to create significant transverse shear strain. Since then, Guccione and colleagues¹³⁷ have successfully modeled end-isovolumic systole in an ovine model of myocardial infarction (see [Inverse Calculation of Myocardial Material Properties](#)).

Our state-of-the-art finite element model is built on the laws of large deformation continuum mechanics and has been described previously.^{137,138} In short, the passive myocardium is modeled by a strain energy function, W , that is anisotropic relative to the local fiber direction:

$$W = 0.5C(e^Q - 1), \quad (18)$$

where

$$Q = [b_f E_{11}^2 + b_t (E_{22}^2 + E_{33}^2 + E_{23}^2 + E_{32}^2) + b_s (E_{12}^2 + E_{21}^2 + E_{13}^2 + E_{31}^2)], \quad (19)$$

where E_{11} is fiber strain, E_{22} is cross-fiber in-plane strain, E_{33} is radial strain, E_{23} is shear in the transverse plane, and E_{12} and E_{13} are shear strain in the fiber-cross fiber and fiber-radial coordinate planes, respectively, and where $C = 0.88$ kPa, $b_f = 18.48$, $b_t = 3.58$, and $b_s = 1.627$.¹³⁹

We have been using a time-varying elastance model in our research work to simulate the active contraction of cardiac muscles.¹³⁷ The time-varying elastance model has the following form:

$$T_0 = T_{\max} \frac{Ca_0^2}{Ca_0^2 + E C a_{50}^2} C_t, \quad (20)$$

where $T_{\max}$ is the maximum isometric tension achieved at the longest sarcomere length and maximum peak intracellular calcium concentration $(Ca_0)_{\max}$, Ca_0 is the intracellular calcium concentration and $E C a_{50}$ is length-independent calcium sensitivity. C_t is the time-varying variable that reads

$$C_t = \frac{1}{2} [1 - \cos(\bar{\omega})], \quad (21)$$

where $\bar{\omega}$ is a time and sarcomere length dependent variable that increases from 0 at the start of contraction to π during peak contraction and then decreases to 0 during diastole. This model is a purely phenomenological model, but it can provide reasonable prediction of cardiac contraction.

Calculation of Stress

Finite element modeling can be used to calculate stress in the atrial and ventricular myocardium, valves, and fibrous structures of the heart. Moreover, finite element

modeling can also predict the end-systolic and end-diastolic pressure-volume relationship, thus predicting the pump function of hearts.

One example is finite element based analysis of the Acorn CorCap Cardiac Support Device (Acorn CSD).¹⁴⁰ The Acorn CSD is a bidirectional woven polyester yarn jacket that is placed around the ventricles of the heart. It is hypothesized that Acorn CSD can reduce the ventricular wall stress, halt, or even reverse the adverse ventricular remodeling process and improve heart function.^{141,142} To study the effect of Acorn CSD on the heart, a biventricular finite element model of a dog with induced dilated cardiomyopathy from rapid pacing was created. The Acorn CSD was modeled as a thin shell layer attached to the epicardium. Prestretching of the device (slack, stretched, strained) was also modeled to study the effects of device implantation on wall stress and heart function ([Fig. 50-15A](#)). The simulations show that Acorn CSD can reduce the end-diastolic myofiber stress substantially (by as much as 78%). The stress-reduction, however, was always accompanied by a decrease in diastolic compliance; LV ED pressure-volume relationship was shifted to the left by 7% without prestretching and 11% with prestretching. End-systolic pressure-volume relationship, however, was not affected by the presence of Acorn CSD. As a result, the Starling's relationship became more depressed, and stroke volume was reduced by 23% without prestretching and 30% with prestretching (see [Fig. 50-15B](#)).¹⁴⁰

Inverse Calculation of Myocardial Material Parameters

Finite element modeling can also be used to calculate diastolic and systolic myocardial material parameters by comparing experimentally measured myocardial strain with strains calculated by the finite element program. The nonischemic BZ surrounding a MI is illustrative. It has been known since the mid-1980s that systolic shortening is depressed in the nonischemic BZ after anteroapical MI,¹⁴³ and Jackson and colleagues⁸³ described infarct extension after anteroapical myocardial infarction in sheep that surprisingly occurs in the face of normal BZ blood flow.⁸³ Guccione and colleagues¹³⁷ performed inverse calculation of the regional systolic contractility parameter, $T_{\max}$, by manually adjusting the regional myocardial contractility until finite element calculated BZ strain was similar to strain measured with MRI and found that regional contractility in the normally perfused BZ is reduced by more than 50%.¹³⁷ More recently, optimization of myocardial material properties by automatic optimization programs has been performed.^{144,145}

Virtual Surgery

Cardiac surgeries often involve tissue resection, suturing, or mechanical device implantation. A unique advantage of finite element modeling over traditional animal experiments is its capability in conducting repeated virtual experiments.

One example is the simulation of mitral annuloplasty performed using a finite element model based on a sheep

FIGURE 50-15 ■ **A**, A biventricular finite element model created for a dog heart with cardiomyopathy induced by rapid pacing. **B**, Left ventricular end-systolic (LV ESPVR) and end-diastolic (LV EDPVR) pressure-volume relationship before (Pre-OP) and after (with different device implantation: LV Only—device wrapped around left ventricle only; ACORN—slack Acorn implantation; Tight ACORN—device was stretched before implantation).

with moderate ischemic mitral regurgitation that was 8 weeks after posterolateral MI.¹⁴⁶ Cardiac MRI was used to measure the heart geometry and systolic cardiac motion. A finite element model that included the left ventricle and the mitral valve was created. Finite element models of saddle shape (Physio II; Edwards Lifesciences, Irvine, Calif.) and asymmetric (IMR ETLogix; Edwards Lifesciences) annuloplasty rings were created and implanted using the so-called virtual suture technique using these two rings (Fig. 50-16). Although both rings were shown to reduce the LV end-systolic myofiber stress in the basal region, the ETLogix ring was found to have a slightly greater ventricular wall-stress reduction effect.¹⁴⁶

Multiscale Modeling

The cardiovascular system is an inherently multiphysics, multiscale system. It involves electrophysiology, cardiac mechanics, and hemodynamics and cover scales including molecular, cell, tissue, organ, and whole body. There are ongoing research efforts to develop multiscale, multiphysics simulation tools that can ultimately simulate the complicated cardiovascular system in an integrated fashion.¹⁴⁷ Potential applications include predicting effects of cardiac surgery (e.g., cardiac resynchronization therapy,¹⁴⁸ passive cardiac constraint¹⁴⁹), studying effects of new drug on the cardiovascular system,¹⁴⁹ revealing mechanisms of cardiac disease,¹⁵⁰ among many others.

One key component in such a multiphysics model is the myofilament active contraction model, which con-

nects electrophysiology to cardiac mechanics. The active contraction model listed in Equations 19 and 20 are not sophisticated enough for such a task. Increasingly sophisticated models are needed; over the years, a number of such models have been developed.¹⁵¹⁻¹⁵⁵ These models often seek to model the cross-bridge directly, the underlying contraction machinery in myocytes, and cycling dynamics through a set of mathematical equations. These models have their roots in the cross-bridge model originally developed by Huxley.¹⁵¹ The original Huxley type models, however, require a set of partial differential equations (PDEs) to model the probability density function of the fractions of attached cross-bridges as a function of cardiac strain. Incorporating these PDE-based cell or tissue level active-contraction models into the organ-level finite element simulations would make the computations prohibitively expensive. To alleviate this problem, ordinary differential equation-based models have been developed. The model developed by Rice and colleagues¹⁵⁴ represents the state-of-the-art. Their model uses a set of ordinary differential equations to approximate the cooperative binding of calcium to troponin and the mean strain of cross-bridges. Their model is able to reproduce many myocyte contraction experiments, including steady-state force-sarcomere length relations, steady-state force-calcium relations, isometric twitches including Ca activation and sarcomere length effects, and cell shortening twitches as a function of activator Ca, among others. The model has been incorporated successfully into large-scale, finite element models to

FIGURE 50-16 ■ Virtual mitral annuloplasty with a Physio II ring (black). **A**, Virtual sutures (cyan) are about to attach a Physio II ring. **B**, Expanded view of region in **A**. **C**, At end-systole after virtual Physio II attachment. A white shaded plane is added to reveal the leaflet coaptation profile. AL, Anterior leaflet; MA, mitral annuloplasty, PL, posterior leaflet; VS, virtual suture. (From Wong VM, Wenk JF, Zhang Z, et al: The effect of mitral annuloplasty shape in ischemic mitral regurgitation: a finite element simulation. *Ann Thorac Surg* 93(3):776–782, 2012.)

analyze the interaction between heart electrophysiology and mechanics.¹⁵⁶

VENTRICULAR INTERACTION AND PERICARDIUM

The right ventricle can affect or interact with the performance of the left ventricle and vice versa.^{157,158} Interaction occurs in two ways. First, the ventricles are connected in series, and a change in output of one will affect the other (series interaction). In addition, direct ventricular interaction occurs because the right and left ventricles are mechanically connected throughout the interventricular septum. Determination of the relative effects of series and direct interaction can be difficult. Slinker and Glantz used a statistical approach,¹⁵⁹ Baker used right heart bypass,¹⁶⁰ and Slater and colleagues¹⁶¹ used an isolated heart preparation to determine the relative contribution of series and direct ventricular interaction.

Ventricular interaction analysis is broken into diastolic¹⁵⁹ and systolic interactions.^{161–163} With an intact

pericardium, Slinker and Glantz¹⁵⁹ determined that direct ventricular interaction is half as important as series interaction at end diastole.⁹ Concentric hypertrophy reduces the effect of direct diastolic interaction further, presumably because the septum is thicker.¹⁶⁴

Ventricular interaction during systole has been measured by causing abrupt changes in right or left ventricular load and measuring the performance of the other ventricle. The ratio of pressure change or gain is usually reported. Typical right-to-left gain is 10%.¹⁶³ Typical left-to-right gain is 4%.¹⁶³ Systolic interaction is increased substantially in dilated cardiomyopathy, with a right-to-left gain of 22% in isolated perfused heart excised at heart transplantation.¹⁶¹

Pericardium

The heart is invested by the pericardium. This double-layered fibrous sac is flexible but not stretchable. The inner (visceral) layer is effectively part of the epicardial aspect of the heart, whereas the outer (parietal) layer fits closely around the heart with a potential space between.

RIGHT VENTRICULAR PRESSURE-VOLUME RELATIONSHIP

A

LEFT VENTRICULAR PRESSURE-VOLUME RELATIONSHIP

B

FIGURE 50-17 ■ The representative data of right ventricle (A) and left ventricle (B) pressure-volume curves obtained during the inflation in various conditions of other heart chambers with and without the pericardium. LA, Left atrium; LV, left ventricle; RA, right atrium; RV, right ventricle. (From Maruyama Y, Ashikawa K, Itoyama S, et al: Mechanical interactions between four heart chambers with and without the pericardium in canine hearts. *Circ Res* 50(1):86–100, 1982.)

Normally, the layers are separated by only a thin film of fluid that acts as a lubricant so that the two surfaces can slide freely. The pericardium is, in turn, surrounded by the intrathoracic cavity, which is normally at subatmospheric pressure, which might help with venous return to the right side of the heart. When discussing the effect of myocardial ischemia on diastolic dysfunction,⁴⁰ the pericardium plays an important role in mediating mechanical effect between ventricles and between atria and ventricles (Fig. 50-17).¹⁶⁵

SURGICAL APPROACH

BLOOD CONSERVATION PROGRAMS

SUMMARY

Following cardiac surgery, multiple quantitative and qualitative hemostatic abnormalities have been described. Preexisting and acquired defects contribute to bleeding. The increasing use of anticoagulants, including antiplatelet agents (clopidogrel, prasugrel, ticagrelor) and new oral anticoagulation (NOAC) agents (dabigatran, rivaroxaban and apixaban), contributes to a preoperative hemostatic defect.¹ These events produce a complex hemostatic alteration that is further complicated by heparin and cardiopulmonary bypass, which cause additional acquired defects in hemostatic mechanisms.² With massive bleeding, dilutional hemostatic changes and hypothermia contribute to coagulopathy.

The management of bleeding following cardiac surgery requires a multimodal approach based on both prevention and therapy.^{3,4} In high-risk patients, intraoperative measures to prevent bleeding can be used to

ameliorate the coagulopathic effects of cardiopulmonary bypass (CPB) and mediastinal suctioning.¹ Tissue injury and stress response can also activate fibrinolysis that produces hemostatic defects. Pharmacologic therapies to treat bleeding and to reduce the need for allogeneic transfusions have been studied extensively in cardiac surgery and will be reviewed.

Multiple preoperative and perioperative interventions can reduce bleeding and postoperative blood transfusion. Preoperative interventions that are likely to reduce blood transfusion include identification of high-risk patients, who should receive available preoperative and perioperative blood conservation interventions, and cessation of antithrombotic drugs (Box 51-1). Perioperative blood conservation interventions include the use of antifibrinolytic drugs, selective use of off-pump coronary artery bypass graft surgery, routine use of a cell-saving device,

BOX 51-1 Predictors of Postoperative Bleeding: Computed Tomographic Surgery

- Advanced age
- Small body size or preoperative anemia (low RBC volume)
- Antiplatelet, antithrombotic drugs
- Prolonged operation (CPB time)—high correlation with OR type.
- Emergency operation
- Other comorbidities (CHF, COPD, HTN, PVD, renal failure)

CHF, Congestive heart failure; COPD, chronic obstructive pulmonary disease; CPB, coronary bypass; HTN, hypertension; OR, operating room; PVD, peripheral vascular disease; RBC, red blood cell.

From Society of Thoracic Surgeons Blood Conservation Guideline Task Force, Ferraris VA, Ferraris SP, et al: Perioperative blood transfusion and blood conservation in cardiac surgery: The STS and The SCA Clinical Practice Guideline. *Ann Thorac Surg* 83(Suppl 5):S27–S86, 2007.

and implementation of appropriate transfusion indications. An important intervention is the application of a multimodality blood conservation program that is institution-based, accepted by all health care providers, and that involves well-planned transfusion algorithms to guide transfusion decisions. This chapter will focus on the spectrum of coagulation changes that occur in cardiac surgery, discuss therapies to prevent and treat bleeding when it occurs, and review blood conservation strategies. Recent concepts in understanding pharmacologic agents will also be reviewed.

NORMAL HEMOSTATIC MECHANISMS

In patients, the vascular endothelium plays a major role in preventing clotting. The vascular endothelium is a nonthrombogenic surface that secretes various substances to prevent coagulation from occurring (Fig. 51-1). Prostacyclin, tissue plasminogen activator, heparan sulfate, antithrombin III, protein C, and endothelium-derived relaxing factor are expressed or secreted to inhibit platelet activation and fibrin formation and to provide vascular patency.⁵ However, if a blood vessel is cut or otherwise damaged, tissue factor and other molecular promoters are released or exposed to provide a thrombotic surface. Exposure of subendothelial vascular basement membrane will activate platelets, and expression of tissue factor will also activate thrombin generation and cellular amplification.⁶ An important additional mechanism for the initiation of the coagulation cascade is platelet activation. Receptors on platelets bind to the damaged blood vessel by forming a bridge with von Willebrand factor (VWF) to initiate platelet adhesion.⁷ Once platelets adhere, they undergo surface receptor changes that cause platelets to aggregate. Once platelets aggregate, they expose factors on their surfaces that provide a template for additional initiation of the coagulation cascade and formation of the early hemostatic plug. Platelets play vital roles in maintaining vascular hemostasis. Any abnormality in platelet

FIGURE 51-1 ■ Hemostasis is the prevention of blood loss; it is accomplished by vasoconstriction and coagulation by cellular and coagulation factors. Undue bleeding is controlled, and the fluidity of the blood is maintained by counterbalances within the coagulation and fibrinolytic systems. Blood vessel injury or disruption, platelet defects, abnormalities of the normally circulating anticoagulants, and fibrinolytic mechanisms can upset the balance between fibrinolysis and coagulation. Blood normally circulates through endothelium-lined vessels without coagulation or platelet activation occurring and without appreciable hemorrhage. Injury to the endothelial cells triggers the hemostatic process, which begins with tissue factor liberation, exposed subendothelial proteins such as collagen, the attachment of platelets (adhesion) to the damaged endothelium or via a von Willebrand factor bridge to allow platelet attachment. The platelets then change form (i.e., activate) and release factors that stimulate the clotting process. They also bind together (i.e., aggregate). At the same time, plasma proteins can react with elements in the subendothelium, activating the contact phase of coagulation. Exposed fibroblasts and macrophages present tissue factor, a membrane protein, to the blood at the injured site, thereby triggering the extrinsic phase of blood coagulation. Under normal conditions, hemostasis protects the individual from massive bleeding secondary to trauma. In abnormal states, life-threatening bleeding can occur or thrombosis can occlude the vascular tree. Hemostasis is influenced by a number of different factors including: (a) vascular extracellular matrix and alterations in endothelial reactivity, (b) platelets, (c) coagulation proteins, (d) inhibitors of coagulation, and (e) fibrinolysis. RBC, Red blood cell; WBC, white blood cell. (From BleedingWeb.com, with permission.)

number or function poses significant risk for postoperative coagulopathy and bleeding.

INHIBITING HEMOSTASIS: ANTICOAGULATION

Heparin

Heparin is the mainstay agent used to prevent clotting during cardiovascular surgery. Heparin is isolated from porcine intestine and previously from beef lung, where it is bound to histamine and stored in the mast cell granules. When heparin is isolated, the purification leads to a heterogeneous mixture of molecules. Heparin is an acidic molecule with side groups, either sulfates or *N*-acetyl groups, attached to individual sugar groups. These structural characteristics are important for producing its anticoagulant activity.^{8,9} Heparin acts as an anticoagulant by binding to antithrombin III (AT), which enhances the rate of thrombin-AT complex formation by

1000- to 10,000-fold. Other factors in the clotting cascade, including factor Xa, are also inhibited by AT.⁹ Anticoagulation thus depends on the presence of adequate amounts of circulating AT.

Heparin anticoagulation can be reversed immediately by removing heparin from AT with the highly basic molecule protamine. Heparin also binds to a number of other blood and endothelial proteins.⁸ Each of these proteins can influence the ability of heparin to act as an anticoagulant, and may, along with AT levels, affect heparin dose responses in patients. Heparin can also produce platelet dysfunction following acute or constant administration, especially with high-dose administration during cardiac surgery. Severe adverse reactions to heparin can also occur because of immune-related causes, including hypersensitivity (allergic) and heparin-induced thrombocytopenia (discussed later).

In January 2008, the U.S. Food and Drug Administration (FDA) received reports of clusters of acute hypersensitivity reactions in patients undergoing dialysis. The Centers for Disease Control and Prevention identified heparin as a common feature of the cases, leading to a recall of affected lots. After the initial recall, there were continuing reports of allergic-type reactions from patients in other clinical settings. The contaminant was recently identified as an unusual, oversulfated form of chondroitin sulfate.¹⁰ Highly charged molecules like this can activate enzymatic cascades in plasma. Activation of kinin pathways produced vasodilation via contact activation, the mechanism of the reported adverse reactions.¹⁰

Protamine Administration and Heparin Reversal

Protamine, the mainstay neutralizing agent, is a basic polypeptide isolated from salmon sperm. Composed mostly of arginine, protamine reverses heparin by a non-specific acid-base interaction (polyanionic-polycationic). Protamine can immediately reverse the anticoagulation effect of unfractionated heparin by nonspecific polyionic-polycationic (acid-base) interactions. Different methods can be used to calculate the reversal dose of protamine, but using a ratio of 1.0 to 1.3 mg protamine to 100 units of the initial dose of unfractionated heparin administered is a useful estimate.⁸ Protamine has the potential to function as an anticoagulant when excessive doses have been administered (Fig. 51-2).¹¹ Additional considerations about protamine and potential adverse effects will be considered later.

Low-Molecular-Weight Heparin

Low-molecular-weight heparin (LMWH) is a derivative of unfractionated heparin producing fragments with a mean molecular weight of approximately 5000 daltons. LMWH fragments of fewer than 18 saccharides retain the critical pentasaccharide sequence needed for formation of a Xa:antithrombin complex.¹² The LMWHs have been suggested to provide a therapeutic benefit because factor Xa generation occurs several steps earlier in the coagulation cascade than thrombin generation; inhibition of Xa has a marked effect on the later steps in

FIGURE 51-2 ■ Excess protamine causes hemostatic dysfunction. Excess protamine contributes to elevations in the activated clotting time (ACT), at greater than the exact dose required to reverse systemic anticoagulation. Overdose of protamine should be strictly avoided. (From Mochizuki T, Olson PJ, Szlam F, et al: Protamine reversal of heparin affects platelet aggregation and activated clotting time after cardiopulmonary bypass. *Anesth Analg* 87:781-785, 1998.)

coagulation. LMWH use is rapidly growing and evolving in cardiovascular medicine because of its long half-life and ease of dosing; however, it can pose a potential problem for cardiac surgical patients because commonly used hemostatic tests are not affected by LMWH. In addition, because these agents are not readily reversed by protamine, they are not suitable anticoagulants for CPB.

Fondaparinux

Fondaparinux (Arixtra), a synthetic pentasaccharide with a duration of action longer than LMWH, selectively binds antithrombin and causes rapid and predictable inhibition of factor Xa.¹³ Fondaparinux is more effective than enoxaparin in preventing venous thrombosis in patients undergoing orthopedic surgery, and it is similar in effectiveness to enoxaparin or unfractionated heparin in patients with pulmonary embolism.¹⁴ Pilot trials involving patients with acute coronary syndromes and those undergoing percutaneous coronary intervention suggest that fondaparinux may be as effective as enoxaparin or safer than unfractionated heparin.¹⁵ The Fifth Organization to Assess Strategies in Acute Ischemic Syndromes (OASIS-5; NCT00139815) trial compared the efficacy and safety of fondaparinux and enoxaparin (Lovenox, Sanofi-Aventis) in high-risk patients with unstable angina or myocardial infarction without ST-segment elevation.¹⁵ The result of this study indicated that fondaparinux reduces the risk of ischemic events similar to enoxaparin, but with less risk of major bleeding.

Warfarin

Warfarin is the most commonly used oral anticoagulant; it is a member of the family of drugs known as *vitamin K antagonists*. Warfarin has major limitations, including slow onset and offset, a narrow therapeutic window, and

metabolism affected by diet, concomitant drug therapy, and genetic polymorphisms. Warfarin also requires careful monitoring.¹⁶ Warfarin is a vitamin K analog that interferes with the transformation of coagulation factors to an active form. Vitamin K is required in the posttranslational carboxylation required for the synthesis of active coagulation factors II, VII, IX, and X. Without vitamin K, these coagulation factors are incapable of chelating calcium that is required for their binding to phospholipid membranes during the normal clotting process, thereby decreasing prothrombin activation. Warfarin also inhibits the carboxylation of protein C and protein S, thus impairing the function of the anticoagulant proteins. Warfarin is often a mainstay in preventing thromboembolic complication in patients with prosthetic heart valves, atrial fibrillation, atrial mural thrombi, deep vein thrombosis, or prior pulmonary embolic problems. Warfarin is rapidly absorbed from the gastrointestinal tract with peak plasma concentrations reached 1 to 4 hours after ingestion; its anticoagulant effect occurs only after a significant decrease in the concentration of normal vitamin K-dependent clotting factors.⁸

The NOAC agent ximelagatran was the first oral anticoagulant, but it was withdrawn from the market in Europe because of hepatic toxicity. A next-generation direct thrombin inhibitor, dabigatran (Pradaxa), is now recommended for atrial fibrillation and VTE prophylaxis.¹⁷ Additional agents include rivaroxaban and apixaban, also approved for paroxysmal atrial fibrillation and VTE prophylaxis. Rivaroxaban and apixaban target factor Xa, whereas dabigatran etexilate inhibits thrombin. Rivaroxaban is a small molecule directed against the active site of factor Xa. After oral administration, all the agents have a rapid onset of action within a few hours. Although monitoring is not required for the NOAC agents, their effects can be determined using readily available coagulation assays.¹⁷ For dabigatran, this includes thrombin times and partial thromboplastin times, and if possible a dabigatran-specific assay that is a diluted thrombin time (HemoClot assay). For rivaroxaban and apixaban, an antiXa assay, similar to LMWH assay but calibrated for the specific drug, is the assay used to measure levels of the Xa inhibitors including edoxaban. All the agents have some renal elimination, but dabigatran is the agent most dependent on renal function, and for all of the NOAC agents dose alterations must be made with renal dysfunction.¹⁷ For more information about the NOAC agents and bleeding, a recent review has discussed this as therapeutic modalities continue to evolve.¹⁷

Heparin-Induced Thrombocytopenia and New Anticoagulants

Heparin-induced thrombocytopenia (HIT) is a potentially life-threatening, adverse effect of heparin produced by antibodies (IgG) induced to the composite antigen of heparin-platelet factor 4 (PF4). Later exposure of seropositive patients to heparin risks forming the heparin-PF4 antigen and immune complexes.¹⁸ These immune complexes bind to platelets via platelet Fc-receptors (CD 32); this produces intravascular platelet activation, thrombocytopenia, and platelet activation with potential

thromboembolic complications that can result in limb loss or death.¹⁸ HIT can occur after 5 to 10 days of heparin therapy, but can occur earlier because of occult heparin exposure from prior hospitalizations or in the cardiac catheterization laboratory.

This serious, yet treatable, prothrombotic disease develops in 1% to 3% of heparin-treated patients and dramatically increases their risk of thrombosis.¹⁹ HIT antibodies (IgM and IgG), occur more often than the overt disease itself. Even without thrombocytopenia, the IgG subclass may be associated with increased thrombotic morbidity and mortality.¹⁹ HIT should be suspected whenever the platelet count drops greater than 50% from baseline more than 4 to 5 days after starting heparin (or sooner if there was prior heparin exposure) or when new thrombosis occurs during, or soon after, heparin treatment, with other causes excluded. When HIT is strongly suspected, with or without complicating thrombosis, heparin should be discontinued and a fast-acting, non-heparin alternative anticoagulant, such as a direct thrombin inhibitor (argatroban or bivalirudin), should be initiated immediately,^{19,20} because HIT is a prothrombotic disease that carries significant morbidity and mortality.

Despite their association with long-term adverse effects, circulating heparin-PF4 antibodies are transient. Should a patient require cardiac surgery and have a history of HIT, antibody titers should be checked. If the patient is currently seronegative, heparin is the anticoagulant of choice.²¹ Bivalirudin has emerged as the agent most studied for use during on- or off-pump surgery in patients with HIT.^{22,23} For prophylaxis in the intensive care unit in patients with HIT, fondaparinux is a potential alternative, but its long duration of effect makes it impractical. Rivaroxaban can have a role for prophylaxis and can be given via a nasogastric tube. Eventually the patient should be switched to warfarin for long-term anticoagulation.¹⁸ Warfarin should not be started until the platelet count has recovered. A minimum of a 5-day overlap of the direct thrombin inhibitor and warfarin should be used before stopping the direct thrombin inhibitor. The role of NOAC agents is yet to be determined.

ACQUIRED PLATELET DYSFUNCTION

Antiplatelet agents are the mainstay therapy for patients with atherosclerotic vascular disease and coronary artery disease. This therapy is based on the role of platelets in causing complications of atherosclerosis.²⁴ Treatment with aspirin reduces the incidence of occlusive arterial vascular events. Aspirin irreversibly acetylates cyclooxygenase and thereby prevents formation of thromboxane A₂, a prostaglandin that mediates activation of more platelets. Clopidogrel is a thienopyridine that inhibits the P2Y₁₂ receptor, and it is widely used in patients with atherosclerotic vascular disease and in patients who do not tolerate aspirin.²⁴ The combination of aspirin plus clopidogrel is recommended after coronary stenting and for up to 9 months after acute coronary syndrome.²⁴ These drugs and other anticoagulant therapies are associated with excessive intraoperative and postoperative bleeding and resultant transfusions in most situations.²⁵⁻²⁷

Patients with thrombocytopenia or with qualitative platelet defects (e.g., renal failure, von Willebrand disease) may represent a group at greater risk for bleeding. Discontinuation of antiplatelet and antithrombotic drugs before cardiac surgery in these high-risk patients should be considered.

Clopidogrel and aspirin therapy result in higher rates of postoperative bleeding, blood product transfusion, and reexploration for mediastinal hemorrhage following emergency coronary artery bypass grafting (CABG).²⁸⁻³⁰ American College of Cardiology/American Heart Association (ACC/AHA) guidelines and the current Society of Thoracic Surgeons (STS) guidelines recommend stopping adenosine diphosphate (ADP) inhibitors 5 to 7 days before cardiac operations, if possible, recognizing that operations sooner than 5 days in patients taking ADP-inhibitors risk increased perioperative bleeding and transfusions.³¹ However, in patients with drug-eluting stents, the abrupt discontinuation of platelet inhibitors may also increase the risk for thrombotic events, and there is little evidence available to guide therapy in this situation. Discussion with all members of the cardiovascular team including cardiologists, cardiac surgeons, and anesthesiologists is recommended. New shorter-acting antiplatelet agents that should soon be available (e.g., cangrelor) might offer an important therapy and a new paradigm for management.³² Changing to a glycoprotein IIb/IIIa inhibitor (GPI) or to a direct thrombin inhibitor might also be an alternative.²⁵

Additional therapeutic agents can produce platelet dysfunction. Platelet glycoprotein (GP) IIb/IIIa complexes are also important in platelet-mediated thrombus formation. GP IIb/IIIa inhibitors have been used less commonly to treat acute coronary thromboses, most likely because of the increasing use of clopidogrel as based on 2013 ST-elevation myocardial infarction (STEMI) guidelines.^{33,34} GP IIb/IIIa (IIb β 3) is a receptor on platelets that binds to key hemostatic proteins, including fibrinogen and VWF, to allow cross-linking of platelets and platelet aggregation. GP IIb/IIIa antagonists block the final common pathway and function as inhibitors of platelet participation in acute thrombosis. Three different agents are available and differ in antagonist affinity, reversibility, and receptor specificity.

The first of these agents, the monoclonal antibody abciximab (ReoPro), was approved for use in percutaneous coronary intervention. Tirofiban (Aggrastat), a nonpeptide, is approved for treatment of acute coronary syndromes (unstable angina or non-Q-wave myocardial infarction). Eptifibatide (Integrilin), a peptide, was approved for use in percutaneous coronary intervention and acute coronary syndromes. The shorter-acting agents tirofiban and eptifibatide are used during coronary intervention. Abciximab, the longer-acting agent, is used with decreasing frequency because of its long half-life and potential for producing thrombocytopenia and bleeding.

HEMOSTATIC TESTING

Hemostatic testing is often used preoperatively to identify patients at risk for bleeding and to define the

presence of any specific defect that could produce bleeding. Because platelet dysfunction is a major cause of bleeding following cardiac surgery, laboratory evaluation of platelet function would provide valuable information. However, most platelet function tests available as point-of-care testing or as laboratory-based testing have not been suitably validated in cardiac surgical patients. In addition, dilutional thrombocytopenia can affect the test results. Better tests of platelet function are needed and should be applied in this patient population to allow for accurate diagnosis of underlying disorders.³⁵

Despite the lack of studies supporting platelet function tests in the perioperative management of cardiac surgical patients, multiple studies have showed that using algorithms based on point-of-care coagulation tests can decrease bleeding and transfusion requirements after cardiac surgery. One important caution is that hemostatic test results can also be abnormal in patients who are not bleeding. Transfusion algorithms can prevent or decrease the empirical administration of hemostatic factors.³⁶ Cardiac surgery services should use transfusion guidelines based on laboratory-guided algorithms, and the possible benefits of point-of-care testing should be tested against this standard.

Risk Factors for Bleeding

Ferraris and colleagues²⁵ summarize variables associated with increased transfusion requirements caused by patient-related, procedure-related, and process-related factors in their inclusive review. However, most studies do not distinguish between red blood cell (RBC) transfusion and hemostatic factor transfusion. Ferraris and colleagues²⁵ identified a high-risk profile associated with increased postoperative blood transfusion. Six variables were identified as important indicators of the risk of bleeding: (1) advanced age, (2) low preoperative RBC volume (preoperative anemia or small body size), (3) preoperative antiplatelet or antithrombotic drugs, (4) reoperative or complex procedures, (5) emergency operations, and (6) certain patient comorbidities. The web site of the review can be found at www.sts.org/sites/default/files/documents/pdf/guidelines/BloodConservationUpdate0311.pdf.

Patient-Related Causes of Bleeding

Certain patients are at greater risk for bleeding, such as those with acquired or congenital coagulopathies, patients scheduled for re-do or complex procedures (e.g., combined valve and coronary revascularization, and aortic dissection with deep hypothermic circulatory arrest). There is evidence that certain patients have an accentuated response to antiplatelet drugs.³⁷ Patients with thrombocytopenia from any cause (defined as platelet count less than 50,000) are at a high risk of excessive bleeding after CABG. Patients with preoperative anemia have a lower starting RBC mass. Anemia in complex ways can also contribute to bleeding. Patients with other congenital or acquired qualitative platelet defects, such as von Willebrand disease, Bernard-Soulier syndrome, and Glanzmann thrombasthenia, are at increased risk of bleeding.²⁵

Acquired qualitative defects occur with hepatic and renal failure, as well as following the administration of some drugs.

Physician-Related Causes of Bleeding

One important factor in surgical bleeding and blood transfusion is the surgeon. Surgical practices differ widely and influence morbidity and mortality.³⁸ Cardiopulmonary bypass times influence platelet function and postoperative bleeding. Meticulous attention to surgical technique and to intraoperative hemostasis will affect bleeding and transfusion requirements. Differences in practice patterns relative to the diagnosis and therapy of postoperative hemorrhage also contribute to variability in transfusion practices.³⁹ Transfusion practices also vary among centers.^{25,40,41}

Procedure-Related Causes of Bleeding

Certain procedure-related factors increase risk for bleeding and perioperative morbidity and mortality. Repeated procedures have higher transfusion rates. The type and urgency of operation are independent predictors for transfusion.⁴²⁻⁴⁵ Cardiopulmonary bypass also influences platelet function and coagulation.⁴⁵ Off-pump cardiac surgery can be associated with an overall reduction in transfusion requirements.^{46,47} Complex, long procedures including those using bilateral internal mammary artery grafts, aortic valve replacement with a pulmonary autograft (Ross procedure), and implantation of ventricular assist devices or artificial hearts, are examples of complex surgeries associated with greater risk of bleeding.²⁵

Drug-Related Causes of Bleeding

Therapy for the prevention and treatment of cardiovascular disease is based on inhibiting clot formation, platelet function, or by causing clot lysis, as previously reviewed.⁴⁸ Patients who are taking these agents and who need surgery are at a greater risk of bleeding as described by Ferraris and colleagues.²⁵ However, in patients undergoing cardiopulmonary bypass while taking warfarin, this might not be the case because of better thrombin inhibition.⁴⁹ Ferraris notes that preoperative antiplatelet and anticoagulant treatment as prophylaxis for coronary occlusive disease is associated with excessive intraoperative and postoperative bleeding as well as resultant transfusion. Therefore, this aspect of patients' preoperative medication regimens must be managed for maximum cardioprotective benefit while minimizing the risk of hemorrhagic complications.²⁵ As noted previously, clopidogrel and aspirin therapy result in higher levels of postoperative bleeding, more transfused blood products, and a higher rate of reexploration for mediastinal hemorrhage following emergency CABG.²⁸⁻³⁰ ACC/AHA guidelines and the current STS guidelines recommend stopping ADP-inhibitors 5 to 7 days before cardiac operations, if possible, recognizing that operations sooner than 5 days in patients taking ADP inhibitors risk increased perioperative bleeding and transfusions.^{31,48}

TRANSFUSION THERAPY AND TRANSFUSION GUIDELINES

The appropriate use of RBC or platelet transfusions continues to be defined in cardiac surgical patients. Guidelines and transfusion algorithms for the management of bleeding in cardiac surgical patients have been reported.^{43,50} Bleeding and reexploration in cardiac surgery are consistently associated with adverse outcomes.⁵¹⁻⁵³ As a result, patients often undergo transfusion in the setting of perioperative bleeding; however, the lack of consistent evidence-based medicine supporting the transfusion decision is illustrated by the wide range of blood product use in CABG surgery. These rates range from 3% to 83% for RBCs and from 0% to 40% for platelets.^{40,41}

Transfusion algorithms have been developed using institution-derived transfusion practices with point-of-care testing to guide therapeutic approaches to bleeding and transfusion. In most studies, point-of-care testing and transfusion algorithms decrease transfusions and improve hemostasis in randomized studies.⁵⁴⁻⁵⁷ It is not certain whether the algorithms, the multidisciplinary approach, or the point-of-care testing are more important in reducing blood product utilization. Ferraris notes that the importance of a multimodality approach is the most important factor rather than the individual components of the process.

The American Society of Anesthesiologists established the Task Force on Blood Component Therapy to develop evidence-based indications for transfusing RBCs, platelets, fresh-frozen plasma, and cryoprecipitate in perioperative settings. Specific guidelines were developed according to an exact methodology.⁵⁸ The recommendations of the task force were reported and can be found at www.asahq.org/For-Members/Practice-Management/Practice-Parameters.aspx and are listed in Box 51-2. Although these guidelines are reported as recommendations, there are also other important considerations regarding the use of specific blood products in cardiac surgical patients. The rationale for transfusion of individual blood components will be presented.

Red Blood Cells

Unfortunately, there is no single minimum acceptable hemoglobin level for all patients. Chronic anemia is better tolerated than acute anemia. With acute anemia, compensatory mechanisms that increase cardiac output and improve oxygen transport depend on the patient's cardiovascular reserve. This may be a problem in cardiac surgical patients with heart failure or flow-restricting lesions. Multiple factors should be considered, including intravascular volume, the presence of active bleeding, and the need for oxygen transport. The anemic cardiac surgery patient who is receiving multiple inotropes and who has an intraaortic balloon pump may require RBCs, although the definition of *anemia* is contentious. The need for transfusion must balance the risks versus the need for oxygen-carrying capacity in recovery from trauma, surgery, or illness as noted in the American Society of Anesthesiologists practice guidelines for

BOX 51-2**Evidence-Based Indications for Transfusing Red Blood Cells, Platelets, Fresh Frozen Plasma, and Cryoprecipitate in Perioperative Settings**

- The risks of bleeding in surgical patients are determined by the extent and surgery, the capacity to control bleeding, the expected rate of bleeding and the outcomes of uncontrolled bleeding.
- RBC transfusions should not be dictated by a single hemoglobin “trigger,” but instead should be based on the patient’s risks of developing complications of inadequate oxygenation. RBC transfusions are suggested to be indicated rarely when the hemoglobin concentration is greater than 10 g/dL and are almost always indicated when it is less than 6 g/dL. The indications for autologous transfusion may be more liberal than for allogeneic transfusion.
- Prophylactic platelet transfusion is ineffective when thrombocytopenia is due to increased platelet destruction. Surgical patients with microvascular bleeding usually need platelet transfusion if the platelet count is less than 50×10^9 cells/L and rarely if it is greater than 100×10^9 cells/L.
- Fresh frozen plasma is indicated for urgent reversal of warfarin therapy, correction of known coagulation factor deficiencies for which specific concentrates are unavailable, and correction of microvascular bleeding when prothrombin and partial thromboplastin times are greater than 1.5 times normal. It is contraindicated for increase of plasma volume or albumin concentration.
- Cryoprecipitate should be considered for patients with von Willebrand disease that is unresponsive to desmopressin, bleeding patients with von Willebrand disease, and bleeding patients with fibrinogen levels less than 80 to 100 mg/dL.

RBC, Red blood cell.

Modified from Practice Guidelines for Blood Component Therapy: a report by the American Society of Anesthesiologists Task Force on Blood Component Therapy. *Anesthesiology* 84:732–747, 1994.

perioperative blood transfusion and adjuvant therapies.⁵⁹ The task force noted in its recommendations that⁵⁹:

[transfusion of] red blood cells should usually be administered when the hemoglobin concentration is low (e.g., less than 6 g/dL in a young, healthy patient), especially when the anemia is acute. Red blood cells are usually unnecessary when the hemoglobin concentration is more than 10 g/dL. These conclusions may be altered in the presence of anticipated blood loss or active critical (i.e., myocardium, central nervous system or renal) or target organ ischemia. Determining whether intermediate hemoglobin concentrations (i.e., 6–10 g/dL) justify or require RBC transfusion should be based on ongoing indications of organ ischemia, potential or actual ongoing bleeding (rate and magnitude), the patient’s intravascular volume status, and the patient’s risk factors for complications of inadequate oxygenation. These risk factors include a low cardiopulmonary reserve and high oxygen consumption.

Hemoglobin triggers for transfusion are not to be taken as absolute indications, and cardiac patients should

be transfused if signs or symptoms of inadequate myocardial oxygen delivery are present.

Blood transfusions are associated with a significant increase in morbidity and mortality. An observational cohort study from the Cleveland Clinic included more than 11,000 patients. This study demonstrated a dose-dependent increase in mortality and morbidity, including renal failure, serious infection, and stroke, in patients receiving RBC transfusions. They concluded that perioperative RBC transfusion is the single factor most reliably associated with increased risk of postoperative morbid events after isolated CABG. These findings were reinforced by a study from the Cardiothoracic Surgical Trials Network. This prospective observational trial of more than 5000 patients found that each RBC transfusion was associated with a 29% increase in the risk of a major infection ($P < 0.001$). An additional retrospective cohort study from a single center including more than 8000 patients found a strong association between RBC transfusion and mortality, infection, length of stay, and cost.⁶⁰ One important aspect of adverse events associated with RBC transfusions relates to the age of RBCs transfused.^{61–63} Prolonged storage is associated with an increased occurrence of complications, and a current National Heart, Lung, and Blood Institute study is underway to investigate this issue in cardiac surgery.

Plasma and Fresh Frozen Plasma

Following collection of a unit of blood, plasma remains after RBC and platelet removal. Plasma contains blood coagulation factors, fibrinogen and other plasma proteins in a volume of 170 to 250 mL that is then frozen and can be stored for up to 1 year. Fresh frozen plasma (FFP) is rarely available; most transfusable plasma is designated FP24, frozen within 24 hours of collection. Before administration, the plasma must be thawed in a waterbath at 37°C, which takes approximately 30 minutes. After thawing, plasma units are stored at 1° to 6° C and are transfused within 24 hours. Plasma should be administered through a component administration set with a 170-µm filter; if not used within 24 hours, it can be relabeled as “thawed plasma” and stored at 1° to 6° C for an additional 4 days. Thawed plasma maintains normal levels of all factors except factor V, which falls to 80% of normal, and factor VIII, which falls to 60% of normal.⁶⁴ Because these levels are above the in vivo threshold for normal hemostatic function for these factors and because FVIII is an acute phase reactant, FP24 or thawed plasma can be used as an acceptable substitute for FFP.⁶⁴

Plasma is used for treating bleeding caused by coagulopathies with a prolongation of either the activated partial thromboplastin time or the prothrombin time (PT)/international normalized ratio (INR) greater than 1.5 times normal, or a coagulation factor assay of less than 25%,⁵⁹ where a factor concentrate is not available or is not indicated. Plasma is often used to reverse the effect of warfarin before surgery or during active bleeding episodes (see following discussion of anticoagulation reversal). When plasma is indicated, it should be administered in a dose calculated to achieve a minimum of 30% of plasma factor concentration. Ten to 15 mL/kg of plasma will generally

result in a rise of most coagulation proteins by 25%–30% (or increases in 0.25 to 0.3 U/mL). A dose of 5 to 8 mL/kg may be adequate to only partially reverse warfarin anticoagulation urgently, because the lowest INR obtainable with plasma is 1.4–1.5.⁵⁹ Plasma is also part of a 1:1 ratio RBC:plasma transfusion algorithm for massive bleeding.

Plasma is overused in cardiac surgery, often because of empiric therapy. A major cause of bleeding after cardiac surgery is platelet dysfunction. Furthermore, the PT and partial thromboplastin times (PTT), which are widely used to evaluate bleeding, have never been demonstrated to reflect bleeding in cardiac surgical patients, and can be abnormal in patients who are not bleeding. These facts would support a restrictive use of plasma in the setting of heart surgery, based on laboratory testing documenting significant abnormalities in appropriate coagulation studies.

Cryoprecipitate

Cryoprecipitate is the insoluble proteins that precipitate when plasma is thawed at 1° to 6° C, and it is named for the process. The residual volume of cryoprecipitate (approximately 15 mL) is refrozen and stored. Cryoprecipitate contains therapeutic amounts of factor VIII:C, factor XIII, VWF, and fibrinogen. Each bag of cryoprecipitate contains 80 to 100 units of factor VIII:C, 150 to 200 mg of fibrinogen, significant amounts of factor XIII, and VWF, including the important high molecular weight multimers. Cryoprecipitate is used to increase fibrinogen levels depleted because of massive hemorrhage or coagulopathy, but also for the treatment of congenital or acquired Factor XIII deficiency.

In Europe, specific fibrinogen concentrates are available for fibrinogen replacement therapy. However, one unit of cryoprecipitate per 10 kg body weight (10 units is a typical adult dose) increases plasma fibrinogen by approximately 50 to 70 mg/dL in the absence of continuing consumption or massive bleeding.⁶⁵ The minimum hemostatic level of fibrinogen is traditionally suggested to be approximately 100 mg/dL. Normal fibrinogen levels are 200 mg/dL and greater, and higher levels of fibrinogen may be important for clot formation (see fibrinogen section). Because cryoprecipitate does not contain factor V, it should not be the sole replacement therapy for disseminated intravascular coagulopathy, which is almost always associated with various factor deficiencies and thrombocytopenia as noted in the guidelines from the American Association of Blood Banks (AABB). Because fibrinogen is an important determinant of hemostatic function and clot strength, fibrinogen levels should be routinely evaluated in bleeding patients, especially after multiple transfusions. Hypofibrinogenemia itself can cause a prolonged PT and PTT, and plasma transfusion alone might not provide sufficient repletion. Cryoprecipitate is likely underused in cardiac surgical patients who are bleeding and refractory to standard plasma and platelets.

Massive Transfusion

Massive transfusion is the acute replacement of more than one blood volume or more than 10 units of packed

RBCs within several hours. In the acute clinical setting, the transfusion of four or more red cell concentrates within 1 hour, when ongoing need is foreseeable, or replacing 50% of the total blood volume within 3 hours may be a more appropriate definition.^{66,67} The most common clinical situation leading to massive transfusion is extensive trauma; however, it also can occur in non-trauma settings during surgical procedures, such as cardiothoracic procedures, associated with large blood loss.^{66,67} Extensive information in this area has been learned from the war in Iraq.^{68–70} Blood transfusion is a main therapy option for treating acute hemorrhage; however, in trauma patients, the ideal solution is fresh whole blood that is not widely available. The etiology of coagulopathy during massive transfusion is complex and it includes dilution, hypothermia, tissue hypoperfusion and ischemia, acidosis, and disseminated intravascular coagulation. Disseminated intravascular coagulopathy can also occur in the setting of cardiac surgery. Treatment of the coagulopathy should include volume replacement including targeted blood component therapy, reestablishment of normothermia, and the correction of acid-base abnormalities. Because of fibrinolysis, an antifibrinolytic should be considered in all cardiac surgical patients. The role of off-label use of prothrombin complex concentrates and recombinant activated factor VII (rFVIIa section) to manage bleeding that cannot be controlled by conventional measures is still evolving⁷¹; however there are interesting studies in cardiac surgical patients supporting its efficacy.⁷²

ADVERSE EFFECTS OF TRANSFUSIONS

The risks of allogeneic transfusion extend beyond viral transmission, and include allergy, alloimmunization, bacterial sepsis, graft versus host disease, transfusion-related acute lung injury (TRALI), renal failure, volume overload, and immunosuppression.^{73–75} Besides possible bacterial contamination, platelet transfusions contain a high concentration of donor white blood cells. Transfusion of donor white blood cells has the potential to produce multiple adverse effects. Cytokines, such as interleukin (IL)-6, IL-8, tissue necrosis factor alpha (TNF- α), and other inflammatory mediators which are concentrated in platelet products could contribute to adverse outcomes.

Platelet concentrates without leukodepletion have been found to be a pro-inflammatory mixture.⁷⁶ Although similar work has not been performed with platelet transfusion, the levels of cytokines, TNF- α , IL-6, and IL-8 are increased 100- to 1000-fold greater than baseline in platelet products.⁷⁶ Since complement and cytokines depress platelet function and increase the release of tissue plasminogen activator, the large influx of proinflammatory mediators from platelet transfusion might mitigate some of the procoagulant function of platelets, increase bleeding, or render platelet transfusions ineffective.⁷⁷

Although active white cells are responsible for producing the high levels of complement and cytokine factors, leukoreduction may be only partially effective in

reducing the immunosuppressive effects of platelets.⁷⁸ In red cell transfusion, leukoreduction can affect T cell activation and expression of key immune molecules on the surface of white cells.⁷⁹ Other mechanisms of immunosuppression not affected by leukoreduction could come into play. The presence of free non-protein-bound iron leads to the activation of white cells (whether allogeneic or autologous).⁸⁰ Furthermore, platelet units treated with leukoreduction and stored at room temperature can increase the number of platelet transfusion units that cause sepsis. The effect of bacterial cell wall material on systemic proinflammatory processes seen during cardiopulmonary bypass is not clear.

Platelet transfusions have long been known to possess a storage lesion leading to decreased effectiveness compared with native circulating platelets.⁸¹ Large percentages of platelets may already be dead and functioning only as cellular shells. This lack of normal cellular activity and regulation may play some role in increasing adverse events. For example, infusion of a platelet product into a patient with an embolic nidus could potentiate thrombus or infarction. Similarly, a prothrombotic potential in a reperfused coronary or cerebral artery could promote thrombus generation if platelet transfusion were additive to thrombotic tendencies. This is best reflected by a study demonstrating platelet transfusions were associated with infection, vasopressor use, respiratory medication use, stroke, and death.⁷⁶

Transfusion-Related Acute Lung Injury

One of the most life-threatening adverse effects of transfusion is TRALI. The incidence of TRALI in cardiac surgical patients may be higher, and a recent report suggests that in-hospital mortality is 13% of patients who develop the complication. TRALI is the leading cause of transfusion-related death via FDA reporting mechanisms.⁸² Clinical presentation of TRALI, in its severe form, is indistinguishable from adult respiratory distress syndrome (ARDS). It is characterized by acute onset (within minutes to 1 to 2 hours after transfusion), bilateral pulmonary infiltrates, and hypoxia without evidence of heart failure.^{73,83,84} TRALI may resolve faster and has a lower mortality rate when compared with ARDS. TRALI usually develops within 6 hours (most often less than 2 hours) of a transfusion, usually resolves within 24 to 72 hours, and has a mortality rate of 5% to 10%. ARDS does not usually develop until at least 24 hours after exposure to one of its risk factors; it often has a duration longer than 72 hours and a mortality approaching 30% to 60%.⁷³ Because of increasing awareness and identification of TRALI and decreases in the incidence of infectious and hemolytic complications of transfusions, TRALI is currently the primary cause of transfusion-associated mortality reported to the FDA and has become a frequent cause of transfusion-related morbidity.⁸⁵ It can occur after the transfusion of various blood components such as RBCs, platelets, and FFP but is most often seen after transfusion of plasma-containing blood components such as FFP and platelets. TRALI can be confused with other transfusion and non-transfusion-related events such as anaphylaxis, hemolysis, circulatory overload, and

cardiac failure. It can manifest with acute shock, florid pulmonary edema, and pulmonary hypertension.^{86,87} Current risk estimates suggest that it occurs in 1 in 8000 to 70,000 units transfused.⁷³

Depending on the causative factor in the transfused component and the inflammatory state of the pulmonary circulation following cardiac surgery, two different but at times complementary and overlapping pathogenic mechanisms are thought to cause TRALI: “the classical-antibody mediated” for most and “the two-hit (inflammatory insult)” for some.^{73,86,88} Most cases of TRALI are due to passive transfer of donor-related antileukocytic antibodies. This occurs far more commonly in multiparous women because of transplacental alloimmunization.⁸⁹ When donor antibodies cross-react with HLA or granulocyte-specific antigens on the patient’s leukocytes,⁷³ priming and activation of granulocytes occur, leading to their pulmonary sequestration and release of proteases, oxidants and leukotrienes. In turn, this causes alveolar epithelial and microvascular endothelial damage resulting in increased permeability and eventual development of noncardiogenic pulmonary edema.

The two-hit model of TRALI is similar to that proposed to cause ARDS. In TRALI, however, the specific causative agent in the blood component is unknown. There is growing evidence associating white cell priming lipids: CD40 ligand released by platelets or several reactive lipid-like substances accumulating in RBCs or platelets during storage. These compounds are referred to as *biological response modifiers* and can be the first pulmonary insult, but are more likely the second. The first insult or hit is generally a systemic inflammatory condition secondary to major surgery, sepsis, trauma, or pulmonary aspiration. The SIRS state causes activation of the pulmonary endothelium and polymorphonuclear lymphocyte (PMN) priming, leading to their sequestration in the pulmonary vasculature. The second hit occurs when the primed PMNs are activated by the biological response modifier in the transfused component. Therapy for TRALI is supportive. Suspected cases of TRALI should be reported to the hospital transfusion service to initiate a suitable investigation. This should include testing of associated donors for antileukocyte and antiplatelet antibodies and typing recipients for HLA antigens (i.e., via leukocytes in a pretransfusion blood specimen or buccal swab technique). If donor leukocyte antibodies that react specifically to the patient’s leukocytes are found, avoiding future transfusion of plasma-containing components from this donor is recommended. The patient, however, is not at an increased risk of TRALI reactions with future transfusion. Recent TRALI mitigation efforts have focused on reducing transfusion of plasma from multiparous donors.⁹⁰

Blood Conservation Strategies

Preoperative Autologous Donation

Preoperative autologous donation is a technique reported in cardiac and noncardiac surgical patients. Because of the urgent need to operate in many patients, the temporal sequence makes this a difficult technique to use in cardiac

surgery. Other questions about the cost-effectiveness of this technique have also been discussed previously. Hospitals and blood banks need specific pathways to isolate and save blood for subsequent operations. Furthermore, in patients with critical cardiac disease, the potential for volume shifts and hemodynamic instability are always concerns. The American Association of Blood Banks guidelines for preoperative autologous donation suggest that no more than 450 mL or 12% of estimated blood volume should be withdrawn at one time, and the patient's hemoglobin concentration should be 11 g/dL or greater at the time of donation. Donations should not be performed more often than every third day. Autologous donation is often performed with preoperative erythropoietin to boost the RBC mass. A recent meta-analysis demonstrated that erythropoietin use with (relative risk [RR] = 0.28; 95% confidence interval [CI], 0.18-0.44; $P < 0.001$) and without autologous donation (RR = 0.53; 95% CI, 0.32-0.88; $P < 0.01$) was associated with a reduction in blood transfusion before cardiac surgery.⁹¹ In addition, a randomized blind control study demonstrated the effectiveness of a very short-term, high-dose erythropoietin protocol in decreasing blood transfusions related to off-pump coronary bypass grafting.⁹¹

Acute Normovolemic Hemodilution

Autologous blood can be collected (15% to 20% of blood volume) in the operating room before operation with accompanying intravascular volume expansion to maintain normovolemia. This technique is often performed in patients with normal to higher red cell masses and calculated intravascular volumes. Reports have showed a 20% to 58% decrease in allogeneic transfusion when autologous blood is retransfused after cardiopulmonary bypass.^{58,109}

Platelet Plasmapheresis

Platelet-rich plasma is harvested using plasmapheresis in the operating room, with RBCs returned through a large-bore central venous access via this catheter. Autologous platelet-rich plasma is retransfused after cardiopulmonary bypass and heparin neutralization. The efficacy of this technique is not well-established and not commonly practiced.^{16,45,52,127}

Red Blood Cell Scavenging Techniques

RBC salvage is commonly used during cardiac surgery.⁹² Shed blood is removed from the surgical field using a specific device and is mixed with an anticoagulant (heparin or citrate). RBCs are separated from plasma and other formed elements by a centrifuge and washed with saline. Salvaged, processed blood is a pure red cell product, diluted with wash solution (typically saline) to a hematocrit between 50% and 60%. Clinicians can also process blood remaining in the extracorporeal circuit in the cell salvage system after separation from cardiopulmonary bypass; however, this technique removes platelets and coagulation factors.

PROHEMOSTATIC AGENTS USED IN SURGERY

Although the standard therapeutic approaches to surgical bleeding are transfusions^{74,76,93}, there are few studies demonstrating their effectiveness.⁹⁴ Bleeding and the need for reexploration can also contribute to mortality.^{44,75} Multiple systemic and topical prohemostatic agents are used during cardiac surgery (Box 51-3). One of the unique aspects in this patient population is the ability to treat preemptively patients for potential causes of bleeding, specifically with antifibrinolytic agents. The multiple agents used will be reviewed in this section.

Antifibrinolytic Agents

Tissue injury during surgery and cardiopulmonary bypass produce direct and indirect activation of complex hemostatic pathways that produce fibrinolysis.^{95,96} There is extensive published research on the use of aprotinin and lysine analogue antifibrinolytics to modify the adverse effects of CPB in adults and pediatric patients.⁹⁷⁻⁹⁹ Efficacy in decreasing bleeding and transfusion is well established, as noted by the recent guidelines published by the Society of Thoracic Surgeons and The Society of Cardiovascular Anesthesiologists.²⁵ Although the safety and efficacy of aprotinin has been studied extensively in randomized placebo-controlled studies,⁹⁹ recent reports from observational databases have posed questions, and it has been removed from the market in North America and Europe.^{100,101}

Lysine Analogs: Epsilon Aminocaproic Acid and Tranexamic Acid

The synthetic lysine analogue epsilon aminocaproic acid (EACA or Amicar) and tranexamic acid (TA) inhibit fibrinolysis by attaching to the lysine binding site of the plasmin(ogen) molecule, displacing plasminogen from fibrin.⁵ Levi reported a meta-analysis of all randomized, controlled trials of the three most often used pharmacologic strategies to decrease perioperative blood loss (aprotinin, lysine analogues [EACA and TA], and

desmopressin). Studies were included if they reported at least one clinically relevant outcome (mortality, re-thoracotomy, proportion of patients receiving a transfusion, or perioperative myocardial infarction) as well as perioperative blood loss. In addition, a separate meta-analysis was performed for studies on complicated cardiac surgery, and 72 trials (8409 patients) met the inclusion criteria.¹⁰² Treatment with aprotinin decreased short-term mortality almost twofold (odds ratio [OR], 0.55; 95% CI, 0.34-0.90) compared with placebo. Treatment with aprotinin and with lysine analogues decreased the frequency of surgical re-exploration (OR, 0.37; 95% CI, 0.25-0.55]; versus OR, 0.44; 95% CI, 0.22-0.90, respectively). These two treatments also significantly decreased the proportion of patients receiving any allogeneic blood transfusion, without increasing the risk of perioperative myocardial infarction.¹⁰²

From the Cochrane database, Henry and colleagues¹⁰³ reported an evaluation of the randomized controlled trials of antifibrinolytic drugs in adults scheduled for nonurgent surgery. Two reviewers independently assessed trial quality and extracted data.¹⁰³ They found 61 trials of aprotinin (7027 participants). Aprotinin reduced the rate of RBC transfusion by a relative 30% (RR = 0.70; 95% CI, 0.64-0.76). The average absolute risk reduction was 20.4% (95% CI, 15.6%-25.3%). On average, aprotinin use saved 1.1 units of RBCs (95% CI, 0.69-1.47) in those needing transfusion. Aprotinin also significantly reduced the need for reoperation for bleeding (RR = 0.40; 95% CI, 0.25-0.66). However, they did not report a decrease in the transfusion of other blood components (i.e., platelets). They also found 18 trials of TA (1342 participants). TA reduced the rate of RBC transfusion by a relative 34% (RR = 0.66; 95% CI, 0.54-0.81). This represented an absolute risk reduction of 17.2% (95% CI, 8.7%-25.7%). TXA use resulted in a saving of 1.03 units of RBCs (95% CI, 0.67-1.39) in those needing transfusion. They found four trials of EACA (208 participants). EACA use resulted in a statistically nonsignificant decrease in RBC transfusion (RR = 0.48; 95% CI, 0.19-1.19). Eight trials made "head-to-head" comparisons between TA and aprotinin. There was no significant difference between the two drugs in the rate of RBC transfusion (RR = 1.21; 95% CI, 0.83-1.76) for TA compared to aprotinin. They also reported that aprotinin did not seem to be associated with an excess risk of adverse effects, including thromboembolic events (thrombosis RR = 0.64; 95% CI, 0.31-1.31) and renal failure (RR = 1.19; 95% CI, 0.79-1.79). The authors infer that aprotinin reduces the need for red cell transfusion and the need for reoperation for bleeding without serious adverse effects. However, the i3 drug study of more than 135,000 patients showed an increased risk of death, renal failure, and heart failure in patients receiving aprotinin. Bayer removed aprotinin from the market in 2008, following the publication of the BART trial.¹⁰⁴ Although fewer studies were reported for TA and EACA, TA appeared to be equally as effective as aprotinin.

Pediatric Patients

Eaton reviews 11 comparative studies of lysine analogues in pediatric heart surgery that included over 1,000

patients.⁹⁷ Most of the studies were prospective, randomized, controlled trials; however, more than half of the studied patients were from a single center (The All India Institute) and included 750 cyanotic patients.⁹³ Two studies involved EACA,^{105,106} three involved TA,¹⁰⁷⁻¹⁰⁹ and one compared both drugs.¹¹⁰ All six studies showed efficacy of antifibrinolytic treatment in decreasing bleeding and transfusion. Twenty-four-hour blood loss was decreased 11% to 44%, and treated patients received 20% to 50% fewer blood transfusions than controls. In addition, sternal closure times were reduced 6 to 25 minutes, and re-exploration rates were improved by 50% to 100%. The benefit of antifibrinolytic treatment is less clear in reoperations. Both EACA and TA appear effective in reducing bleeding and transfusion in cyanotic patients, but the efficacy in other high-risk and mixed populations is not as well proved. A review of antifibrinolytic agents in pediatric patients describes these data in detail.⁹⁷

Protamine

Protamine is a polypeptide composed of approximately 70% arginine residues, and thus has a high pK_a to reverse the acidic molecule heparin by forming a simple acid-base interaction.¹¹¹ Protamine does not reverse low-molecular-weight heparin. Following administration, protamine rapidly reverses heparin as noted by return of activated clotting times, but with marked elevations in plasma concentrations of prothrombin fragment 1.2, thrombin-antithrombin complex, and fibrin monomer.

Protamine can cause adverse reactions including anaphylaxis, acute pulmonary vasoconstriction and right ventricular failure, as well as hypotension.¹¹¹ Different reactions to protamine have been reported ranging from minimal cardiovascular effects to life-threatening cardiovascular collapse. Life-threatening reactions to protamine probably represent true anaphylactic or allergic manifestations, mediated by immunospecific antibodies. Patients with diabetes are at an increased risk for adverse reactions because of the presence of neutral protamine Hagedorn (NPH), which contains insulin and protamine, causing increased protamine sensitization.¹¹¹ Stewart reported a 27% incidence of reactions following cardiac catheterization in insulin-dependent diabetics who were also receiving NPH insulin preparations. Other reports do not corroborate the extreme results of Stewart.¹¹² In a study of 1551 cardiac surgery patients, we reported that the incidence of reactions to protamine was 1 in 50 among patients with NPH-insulin-dependent diabetes, compared with 1 in 1501 among the non-NPH-insulin-dependent patients with diabetes.¹¹³ A subsequent prospective study found that reactions occurred in less than 1% (1/160) of patients with NPH-insulin-dependent diabetes.¹¹⁴ Individuals reported at risk for protamine reactions include patients with vasectomy, multiple drug allergies, and prior protamine exposure.¹¹¹ Levy reported the incidence of life-threatening reactions in cardiac surgical patients ranged from 0.6% to 2% in patients at risk.^{113,114} Currently, there are no clinically available alternatives to protamine.

Desmopressin

Desmopressin (DDAVP) is the V_2 analog of arginine vasopressin that stimulates the release of ultra-large VWF multimers from endothelial cells. DDAVP increases VWF and associated factor VIII levels. In addition, desmopressin induces release of normal VWF from cellular compartments.¹¹⁵⁻¹¹⁸ Von Willebrand disease (VWD) is the most frequent inherited bleeding disorder and is due to quantitative (types 1 and 3) or qualitative (type 2) defects of VWF.¹¹⁹ DDAVP is the treatment for type 1 VWD. DDAVP is not effective in type 3 and in severe forms of types 1 and 2 VWD. Plasma virally inactivated VWF concentrates should be used in bleeding episodes, surgery, and secondary long-term prophylaxis.¹¹⁹

DDAVP should be administered by slow intravenous infusion at a dose of 0.3 μ g per kilogram to avoid hypotension.^{120,121} An initial study reported that desmopressin reduced blood loss and transfusion needs by approximately 30% during complex cardiac surgery.¹²²⁻¹²⁴ Later efforts to reproduce these findings were variable; most did not confirm the marked benefit originally reported.^{121,125} Mannucci noted that there have been 18 trials of desmopressin in 1295 patients undergoing cardiac surgery that show a small effect on perioperative blood loss (median decrease, 115 mL).¹¹⁸ Although DDAVP helps to reduce perioperative bleeding, its effect is too small to influence other, more clinically relevant outcomes such as the need for transfusion and reoperation. Levi noted the rate of myocardial infarctions in patients receiving DDAVP was twice that compared with patients who received placebo, with no improvement in clinical outcomes.¹²⁶ However, another review evaluating 16 trials of DDAVP in cardiac surgery and in other high-risk operations showed that the rate of thrombosis did not differ significantly between patients who received DDAVP and patients who received placebo (3.4% versus 2.7%).¹²⁷

Fibrinogen

Fibrinogen is an important and often neglected coagulation factor that plays a major role in producing effective clot in surgical patients. Fibrinogen levels represent an important predictor of perioperative bleeding.^{94,128} Blome and colleagues¹²⁹ reported that the fibrinogen level after cardiac surgery bypass was inversely correlated with postoperative chest tube drainage volume, but bleeding was not correlated with platelet count, prothrombin time, or activated partial thromboplastin time. Decreased fibrinogen levels are reported to affect the severity of postpartum bleeding adversely. During the third trimester of pregnancy, fibrinogen levels are elevated to greater than 400 mg/dL. For each decrease in fibrinogen level of 100 mg/dL in parturients, odds for bleeding were 2.63-fold higher.¹³⁰ These clinical data highlight critical roles of fibrinogen in the prevention of excessive bleeding. Adequate plasma levels ($\approx$ 200 mg/dL) need to be achieved before administering other procoagulant interventions (e.g., FVIIa). Fibrinogen can be efficiently repleted by human plasma-derived fibrinogen concentrate; otherwise, fibrinogen-rich cryoprecipitate can be given (one

FIGURE 51-3 ■ Thromboelastography recordings obtained with the ROTEM device after the addition of recombinant factor VIIa (rFVIIa), fibrinogen, or both in the presence of tissue-type plasminogen activator in volunteer plasma. Tissue-type plasminogen activator was added to stimulate fibrinolysis. The maximal clot firmness (the width of clot tracing) was only improved after the addition of fibrinogen. The onset of clotting was shorter after the addition of rFVIIa, but the extent of lysis (i.e., decreased clot firmness) was increased in contrast to the samples with fibrinogen. Fibrinolysis was observed after the addition of rFVIIa and fibrinogen, and the clot structure was improved after the addition of an antifibrinolytic aprotinin. rFVIIa was used in a final concentration 1.5 μ g/mL. Fibrinogen was used in a final concentration 100 mg/dL. (From Tanaka KA, Taketomi T, Szlam F, et al: Improved clot formation by combined administration of activated factor VII [NovoSeven] and fibrinogen [Haemocomplettan P]. *Anesth Analg* 106:732-738, 2008.)

unit per 10-kg increases fibrinogen by 50 to 70 mg/dL). In Europe, fibrinogen concentrates are available and cryoprecipitate is not used. Data are accumulating in cardiac surgery demonstrating the effectiveness of fibrinogen in reducing bleeding in cardiac surgical patients as recently reviewed.¹³¹ However, fibrinogen is a critical part of a multimodal therapeutic plan as shown (Fig. 51-3).¹³²

Recombinant Factor VIIa

Recombinant activated factor VII (rFVIIa) is an important example of applying recombinant technology; the ability to synthesize in large quantities specific molecules that are critical for specific biological functions. Although multiple mechanisms for its efficacy have been described, rFVIIa is thought to act locally at the site of tissue and vascular-wall injury by binding to exposed tissue factor, forming small amounts of thrombin that are sufficient to activate platelets.¹³³ The activated platelet surface can then form a template on which rFVIIa directly or indirectly mediates further activation of FXa, eventually forming much more thrombin and leading to the conversion of fibrinogen to fibrin.^{129,130,134,135} In perioperative patients, rFVIIa is an off-label approach to treating refractory bleeding, which is approved in the United States only for treating bleeding in patients with

BOX 51-4 Rescue Therapy with Recombinant Factor VIIa in the Perioperative Setting: Off Label

- Severe (1 L/hr) or life-threatening (central nervous system) bleeding without surgical source of bleeding
- Marginal response to routine hemostatic therapy (i.e., platelets, fresh frozen plasma, cryoprecipitate, desmopressin)
- Judicious use with cardiovascular disease, disseminated intravascular coagulopathy, or ongoing activation (cardiopulmonary bypass)
- Consider lower dose (30 µg/kg)
- Patients with multiple antibodies and platelets or factors not available

Modified from Levy JH: Pharmacologic methods to reduce perioperative bleeding. Transfusion 48:31S–38S, 2008; Goodnough LT, Lublin DM, Zhang L, et al: Transfusion medicine service policies for recombinant factor VIIa administration. Transfusion 44:1325–1331, 2004; and Despotis G, Avidan M, Lublin DM: Off-label use of recombinant factor VIIa concentrates after cardiac surgery. Ann Thorac Surg 80:3–5, 2005.

hemophilia who had antibodies (inhibitors) inactivating infused allogeneic factor VIII or IX concentrates.¹³² Numerous reports described its use in patients following major hemorrhage from surgery, trauma, or spontaneous intracranial hemorrhage.

Initial clinical trials reported that the incidence of thrombotic complications among patients who received rFVIIa was relatively low and similar to that among patients who received placebo.¹³⁶ However, most case reports administering rFVIIa as rescue therapy (Box 51-4) include patients who have impaired coagulation, have received multiple transfusions, and are at a high risk for adverse events. The complex role that transfusion therapy has in producing adverse outcomes is increasingly being noted in the literature. A report using the FDA MedWatch database noted thromboembolic events in patients with diseases other than hemophilia in whom rFVIIa was used on an off-label basis, and included 54% of the events as arterial thrombosis (e.g., stroke, acute myocardial infarction).¹³⁷ Venous thromboembolism (mostly venous thrombosis or pulmonary embolism) occurred in 56% of patients who had thromboembolic events. Thromboembolism was considered the probable cause in 72% of the 50 reported deaths. It is not clear to what extent the clinical conditions requiring the use of rFVIIa may have contributed to the risk of thrombosis.¹¹⁵ Other major issues about rFVIIa include cost and dosing strategies, which are not evidence-based. Randomized studies in cardiac surgery using moderate dosing raised safety concerns; given these and other indications of adverse thrombotic outcomes, further randomized studies are unlikely. However, Mannucci and Levi¹¹⁵ note that rFVIIa has expanded the treatment options for acute hemorrhage in patients with conditions other than hemophilia,¹¹⁵ and use for refractory bleeding continues. In 2009, a phase II dose-escalation trial of activated factor VII was published using 40 µg/kg or 80 µg/kg dosing and a control group. Primary endpoints were adverse events. Secondary events were reoperation rates, blood loss, and

transfusion requirement. While there were more adverse events in the 40-µg/kg group (14%; $P = 0.25$) and the 80 µg/kg arm (12%; $P = 0.11$) versus control (7%), these differences were not statistically significant.

Reversal of Vitamin K Antagonist-Associated Coagulopathy

Older, complex, critically ill patients often receive warfarin and derivative agents for thromboembolic prophylaxis of atrial fibrillation or valvular heart disease. After stopping therapy, the anticoagulant effect of vitamin K antagonists require days to return to baseline, but can be more rapidly reversed by pharmacologic agents such as vitamin K, FFP, and other novel therapies. When warfarin therapy needs to be reversed, patients are given vitamin K at doses of 10 to 20 mg orally or intramuscularly. Although the prothrombin time can reverse in 24 to 48 hours if the patient does not have underlying liver disease, reversal is also dependent on the level of anticoagulation, which affects factor levels. In patients requiring urgent or emergency procedures, the anticoagulation effects cannot be readily reversed by administering FFP. Even after multiple units, the lowest INR to be obtained is approximately 1.5.

Prohemostatic agents are often needed urgently to reverse the anticoagulant effect of these drugs in the perioperative setting. Prothrombin complex concentrates (PCCs) have been originally developed for repleting factor IX in hemophilia B, and they contain a standardized amount of factor IX along with various amounts of other vitamin K-dependent factors (prothrombin, FVII, FX, proteins C and S). PCCs are recommended in guidelines as primary treatment for reversal in patients with life-threatening bleeding and an elevated INR, and rFVIIa may be considered as an alternative.¹³⁸ Evidence suggests that, compared with FFP, PCCs offer quicker INR correction and improved bleeding control; they also have a lower infusion volume and are more readily available without cross matching.^{139–142} Although there are historical concerns regarding potential thrombotic risk with PCCs, present-day PCCs are much improved.¹⁴¹ Although clinicians still use rFVIIa for urgent reversal of warfarin and other vitamin K antagonists, PCCs are more effective in correcting the underlying coagulopathy.^{48,141} Although many patients requiring rapid reversal of warfarin are currently treated with FFP, PCC should be considered as alternative therapy in this setting. A four-component PCC was approved for use in the United States (prothrombin complex concentrate [Kcentra]) in 2013.¹⁴²

Topical Hemostatic Agents

Topical agents are often used as adjunctive measures to promote surgical hemostasis; they include microfibrillar collagen, bovine collagen-based composite mixed with autologous plasma, and fibrin sealants (Box 51-5). Gelatin sponge, or Gelfoam, is purified pork skin gelatin that is intended to augment contact activation and hemostasis. Gelatin substances absorb multiple times their weight in blood. Gelfoam can be applied dry, directly to the

BOX 51-5 Topical Hemostatic Agents

- Gelatin sponge: Gelfoam, purified pork skin gelatin (e.g., Jell-O)
- Oxidized regenerated cellulose: Surgicel or Oxycel, from α -cellulose (plant-based) in knit or microfibrillar form
- Microfibrillar collagen: Avitene (collagen derived from bovine skin)
- Topical thrombin: bovine-derived, human, and human recombinant (Recothrom)
- Fibrin sealants: Tisseal, Crosseal (human fibrinogen, bovine thrombin, aprotinin)

From BleedingWeb.com, with permission.

bleeding surface and pressure applied, or wet in saline. Oxidized regenerated cellulose, also known as Surgicel or Oxycel, is derived from α -cellulose and is plant-based. Surgicel is in “knit form,” and Oxycel comes in a microfibrillar form. These cellulose derivatives are acidic and are thought to cause some small vessel contraction and contact activation. They require an intact hemostatic system to be effective. These agents need to be applied dry, and they absorb within 4 to 8 weeks. Microfibrillar collagen (Avitene) is commonly used in a light flour form, but is also available in a nonwoven web form. This collagen preparation is derived from bovine skin and binds avidly to blood surfaces. A dry field is not necessary to apply the collagen. Avitene causes minimal swelling compared with Gelfoam. Like the other agents, Avitene enhances contact activation. Collagen sponges, derived from bovine Achilles tendon or bovine skin, are similar to Avitene and have the same mechanism of action derived from bovine Achilles tendon or bovine skin, and they work basically the same way.

Other types of hemostatic agents are based on topical thrombin used alone or in combination with other agents. In 1999, Floseal was made available; it consists of bovine thrombin plus cross-linked gelatin granules mixed together. Floseal attained higher rates of hemostasis and shorter times to hemostasis than other hemostatic agents did in a prospective, randomized single-center trial. Fibrin sealants, including Tisseal and CoSeal are combinations of purified human fibrinogen, bovine or human thrombin, with an antifibrinolytic agent to prevent clot lysis.¹⁴³ These agents require a relatively dry field. There are also institutionally based autologous fibrin sealants, in which fibrinogen and thrombin are taken from a patient's plasma or platelet gel from autologous platelets is obtained.

One of the major problems with bovine thrombin is the formation of antibodies that can cross-react with patient thrombin and factor V to produce complications ranging from anaphylaxis to bleeding.¹⁴⁴⁻¹⁵⁰ As a result, both purified and recombinant human thrombin has been developed. Human thrombin is available as Evithrom, and recombinant thrombin is available as Recothrom.¹⁵¹ Human thrombin is purified by extensive means, but it still carries the label “May carry a risk of transmitting infectious agents such as viruses and theoretically, the Creutzfeldt-Jakob disease (CJD) agent,

despite manufacturing steps designed to reduce the risk of viral transmission.”

Overall, Gelfoam, Surgicel, Avitene, and these collagen sponges can be stored at room temperature, and they are ready to use out of the box. Floseal requires a 2- to 5-minute preparation time. Thrombin is mixed with calcium, and the combination is added to the gelatin granules. Fibrin sealants must be kept in cold storage and thawed before use. The preparation time can be up to 20 to 30 minutes.

SURGICAL APPROACH

Transcatheter approaches to performing cardiac surgical procedures are associated with lower transfusion rates. A study comparing transcatheter versus surgical aortic valve replacement in high-risk patients demonstrated a significant reduction in major bleeding events in the TAVR group (9.3% versus 19.5%; $P < 0.001$). Similarly, a meta-analysis comparing endovascular aortic repair versus open surgical repair of descending thoracic aortic disease demonstrated a significant reduction in transfusion rates and in the incidence of reoperation for bleeding.

BLOOD CONSERVATION PROGRAMS

Evidence is accumulating in support of the efficacy of targeted programs to reduce blood utilization safely. Brevig and colleagues published their experience with the creation of a multidisciplinary program at a community hospital.¹⁵² This retrospective, single-center study included more than 2500 patients with a primary outcome of RBC transfusions. Self-identified essential features of their program included surgeon attention to hemostasis, perfusion strategies to reduce hemodilution, a blood conservation coordinator, a treatment protocol for anemia management, a physician champion, an institutional multidisciplinary commitment to reduce transfusion, and review of provider-specific data. They demonstrated a significant reduction in the percentage of patients receiving transfusions. A recent study from the Virginia Cardiac Surgery Quality group examined the effects of a blood conservation initiative with defined transfusion triggers on risk-adjusted mortality and morbidity. This retrospective, multicenter study involved more than 14,000 CABG patients. Intraoperative (24% versus 18%; $P < 0.001$) and postoperative (39% versus 33%; $P < 0.001$) transfusion rates were reduced in the post-guideline period. In addition, the reduced transfusion rates were associated with lower mortality rates and a lower incidence of pneumonia, prolonged ventilation, and renal failure. In Michigan, a multicenter quality collaborative focused on blood use as a quality metric. In 2008, institutional blood transfusion rates were added to the list of measures. There was also an educational program focused on blood transfusion risks and methods and benefits of blood conservation. The primary outcome was transfusion rates of RBCs, FFP, and platelets. Transfusion rates of all products decreased from 2008 to 2012 ($P < 0.001$ for all). This result was associated with decreased rates of deep sternal

infection, reoperation for bleeding, prolonged ventilation, renal failure, and length of stay in the intensive care unit. There was no change in mortality. Additional evidence in support of the safety of blood conservation programs comes from the Cleveland Clinic experience with Jehovah's Witnesses undergoing cardiac surgery. More than 300 Jehovah's Witnesses underwent cardiac surgery over an 18-year period. When compared with matched patients who received transfusions, Witnesses had fewer complications and a shorter length of stay. Hospital mortality was similar in the two groups (3.1% versus 4.3%; $P=0.4$). The evidence indicates that cardiac surgery with blood conservation is associated with better results than conventional care.

SUMMARY

Cardiac surgical patients are at significant risk for bleeding. Certain patients are at a greater risk for bleeding and a need for transfusions. Variables that are important risk factors include (1) advanced age, (2) low preoperative RBC volume (preoperative anemia or small body size), (3) preoperative antiplatelet or antithrombotic drugs, (4) reoperative or complex procedures, (5) emergency operations, and (6) certain noncardiac patient comorbidities. Perioperative interventions are likely to reduce bleeding and the need for blood transfusion. Blood conservation interventions include use of antifibrinolytic drugs, selective use of off-pump coronary artery bypass graft surgery, routine use of a cell-saving device, and implementation of appropriate transfusion indications. An important intervention is the application of a multimodality blood conservation program that is institution-based and is accepted by all health care providers, and that involves well-planned transfusion algorithms to guide transfusion decisions. Evidence-based blood conservation techniques include (1) drugs that increase preoperative blood volume (e.g., erythropoietin) or decrease postoperative bleeding (e.g., antifibrinolytics), (2) devices that conserve blood (e.g., intraoperative blood salvage and blood-sparing interventions), (3) interventions that protect the patient's own blood from the stress of operation (e.g., autologous predonation and normovolemic hemodilution), (4) consensus, institution-specific blood transfusion algorithms supplemented with point-of-care testing, and most importantly, (5) a multimodality approach to blood conservation combining all the above.

CONCLUSION

Cardiac catheterization and coronary angiography are essential tools in the diagnosis and evaluation of coronary and valvular heart disease, with several million procedures performed annually in the United States. Significant technological advances have occurred since the insertion of the first intravascular catheter by Werner Forsman in the 1920s,¹ the first selective coronary catheterization by F. Mason Sones in 1956,² and the first coronary angioplasty by Andreas Grüntzig in 1977.³ Today, angioplasty and stenting are the predominant modes of catheter-based intervention in all major vascular beds.

Coronary artery disease (CAD) is the leading cause of death in the United States,⁴ a statistic that has remained relatively stable over several decades despite landmark improvements in primary and secondary prevention as well as rapid catheter-based emergency management of acute coronary syndromes.⁵ Morbidity from CAD is

likewise a major public health issue because of increasing numbers of survivors with resultant congestive heart failure (CHF).⁶

DIAGNOSTIC CATHETERIZATION TECHNIQUES

Indications

The most common indications for the performance of diagnostic cardiac catheterization are to assess for the presence, extent, and severity of clinically suspected CAD, or to evaluate the severity of noncoronary valvular or myocardial disorders, particularly when a surgical or percutaneous intervention is contemplated.⁷⁻¹¹ The decision to perform invasive coronary angiography or

BOX 52-1 Relative Contraindications to Cardiac Catheterization and Coronary Angiography

- Active bleeding or severe anemia
- Severe coagulopathy
- Advanced renal dysfunction
- Uncontrolled hypertension
- Significant electrolyte imbalance (e.g., severe hypokalemia)
- Active infection or unexplained fever
- Acute or subacute stroke
- Decompensated heart failure preventing patient positioning or oxygenation

BOX 52-2 Possible Complications of Cardiac Catheterization

- Death: 0.1% to 0.2%
- Myocardial infarction: 0.1%
- Stroke: <0.4%
- Vascular complication: 2% to 5%
- Severe contrast reaction: <0.2%
- Renal failure: 1% to 30%

hemodynamic testing should be based on a careful analysis of the indications, risk-to-benefit ratio, and alternatives, to best identify patients who will benefit most from the procedure.¹²

Contraindications

There are few absolute contraindications to cardiac catheterization other than patient refusal. The principle relative contraindications include active bleeding, severe anemia, coagulopathy, uncontrolled hypertension, significant electrolyte abnormalities, advanced renal dysfunction, active infection, decompensated heart failure precluding adequate patient positioning, and recent stroke (Box 52-1).¹¹

Complications

The overall risk of major complications resulting from diagnostic cardiac catheterization is less than 1%, although non-major vascular access site complications such as non-life-threatening bleeding or pseudoaneurysm formation can be as high as 3% with femoral artery access in patients with peripheral arterial disease.¹³ In addition, catheter manipulation in atherosclerotic vessels can lead to emboli (thrombus, atherosclerotic debris, calcium, or air) or clot formation, potentially leading to stroke, myocardial infarction, worsening renal function, or CHF (Box 52-2).

CORONARY ANGIOGRAPHY

Coronary angiography is performed by selective injection of the coronary arteries. In rare instances, nonselective coronary imaging or aortography can also be performed

to identify ostia of native coronary arteries that are difficult to locate (predominantly those with anomalous origins) or bypass grafts.

Vascular Access

The most common access site for coronary angiography in the United States remains the femoral artery, although axillary, brachial, and radial approaches can also be used.¹⁴ The transradial approach to cardiac catheterization, first introduced by Lucien Campeau in 1989,¹⁵ is being used increasingly for diagnostic coronary angiography and percutaneous coronary interventions, primarily because of its lower bleeding rates, reduced access site complications, improved patient comfort, and reduced length of stay and hospital costs.¹⁶⁻²⁰ Although adoption of radial access in the United States has been slow compared with other parts of the world, the number of procedures performed transradially increased from 3% in 2008 to more than 8% in 2011, and it is predicted to rise to more than 20% in 2015.²¹ Internationally, there are many centers that currently perform more than 95% of procedures via the transradial approach.

Challenges that are unique to the transradial approach include difficulty traversing a spastic radial artery or a tortuous radiobrachial or thoracic artery (Fig. 52-1).^{17,22} Postprocedural permanent radial artery occlusion occurs infrequently,²³ and it is typically clinically silent because of the dual blood supply to the hand. Radial occlusion can, however, affect future use of the radial artery as a bypass conduit.²⁴ Laboratory studies have demonstrated reduced flow-mediated dilation and intimal hyperplasia, which could theoretically reduce radial artery graft patency in the radial arteries of patients who have undergone prior transradial catheterization.²⁵⁻²⁷

The most common method of vessel cannulation is the Seldinger technique.²⁸ In this technique, the vessel of interest is punctured, and a guidewire (usually an 0.035-inch J-tipped wire) is advanced into the vessel.^{29,30} The J-tipped wire then serves as a rail over which a dilator and sheath enter the vessel. For radial artery catheterization, a micropuncture needle with a 0.018-inch wire and a specialized radial sheath with a hydrophilic coating are used instead. Once access is obtained, the sheath acts as an entry point for passage and exchange of all catheters and devices, generally over the 0.035-inch J-tipped wire. After a catheter is advanced into the ascending aorta, the guidewire is withdrawn and the catheter is connected to a manifold system that allows, in a closed system, the ability to simultaneously inject contrast and transduce pressures at the catheter tip. The catheter is then cleared and advanced, with continuous pressure monitoring, into the ostia of the coronary artery. If the pressure waveform dampens or the catheter fails to backbleed, a significant ostial coronary artery lesion, unfavorable catheter engagement angle, catheter kinking, or entrapment of thrombus or atheroma should be suspected. Care should always be taken during engagement and injection of any coronary artery to avoid potentially fatal complications such as introduction of air, vessel dissection, intubation of a critical left main lesion, or disruption of atherosclerotic lesions.

FIGURE 52-1 ■ **A**, Radial artery loop. **B**, Tortuosity of the right subclavian artery. **C**, Venogram of congenitally absent right superior vena cava (SVC) and persistent left SVC (arrow) performed during attempted right heart catheterization via the right antecubital vein.

FIGURE 52-2 ■ Representative tip configurations and catheters used in diagnostic coronary angiography: Judkins right (JR) and left (JL) catheters. The primary (*upper arrow*) and secondary (*lower arrow*) curves of the Judkins left catheter are shown; Amplatz right (AR) and left (AL) catheters; multipurpose (MP) catheter; internal mammary (IM) catheter; and left coronary bypass (LCB) catheter.

Accurate delineation of coronary anatomy and identification of coronary stenoses is dependent on the acquisition of multiple orthogonal views to enable full visualization of all coronary segments without foreshortening or overlap. Preshaped coronary catheters are used to engage the left and right coronary arteries selectively. The choice of a specific diagnostic catheter is influenced by the site of arterial access, the size of the aortic root, and the anatomic take-off of the coronary arteries. Typically, a Judkins left 4-cm catheter (JL4) and a Judkins right 4-cm catheter (JR4) are used as the default catheters for left and right coronary angiography, respectively, via the femoral approach (Fig. 52-2). Transradial coronary angiography can generally be performed using femoral catheter curves without difficulty; however, a shorter JL curve and longer JR curve may be required for a proper

fit from the right radial approach. In addition, several universal catheters are also available for transradial use for both right and left coronary angiography, and often left ventriculography as well, such as the Kimny, Jacky, or Tiger catheters.

Left Coronary Angiography

Safe cannulation of the left main (LM) coronary ostium is best ensured by confirming that the pressure tracing is neither dampened nor ventricularized. The default JL4 catheter is successful in engaging the left main ostium approximately 80% of the time. If the aortic root is dilated or unusually narrow, longer or shorter catheters (JL5 or JL3.5) may be required, whereas a posterior origin of the left main is often best imaged using an Amplatz catheter.

Coronary anatomy is defined during angiography with contrast injections of 8 to 10 mL during cineangiography runs. The imaging angles used during angiography permit three-dimensional reconstruction of the coronary anatomy using orthogonal views to visualize each artery and its ostial, proximal, mid, and distal segments in multiple planes.

The left coronary system begins with the left main, which terminally bifurcates into the left anterior descending (LAD) and left circumflex (LCX) coronary arteries. In approximately one third of patients, the LM terminally trifurcates into the LAD, the LCX, and an intermediate branch (the ramus intermedius coronary artery) that supplies much of the left ventricular free wall.³¹ The LAD artery gives off septal branches as it courses down the interventricular groove and diagonal branches, which supply the anterolateral free wall of the left ventricle. The LCX, as it courses in the atrioventricular (AV) groove, gives off obtuse marginal branches that supply the lateral free wall of the left ventricle (Fig. 52-3).

Right Coronary Angiography

The right coronary artery (RCA) is usually engaged with a JR4 catheter. The RCA courses in the interventricular groove and gives off acute marginal and right ventricular branches that supply the right ventricular free wall. The RCA terminally bifurcates at the crux of the heart to form the right posterolateral branch (PLB) and the right posterior descending artery (PDA), which supply the inferolateral segments of the left ventricle, the inferior wall, and posterior interventricular septum (see Fig. 52-3).

The dominance of the coronary circulation depends on which artery supplies the posterior circulation—the PDA or the PLB. Approximately 60% of the population is right-dominant (the RCA provides both of these branches), 25% is codominant (the RCA supplies the PDA and the LCX gives off the PLB), and 15% is left-dominant (the LCX provides both of these branches).³²

Coronary Anomalies

Several coronary anomalies (Fig. 52-4) exist in addition to the typical coronary anatomy described earlier. Most are simple anatomic variants, such as dual ostia for the LAD and LCX, whereas others are congenital abnormalities, such as an anomalous origin of the LCX from the RCA.³³⁻³⁶ Most of these congenital anomalies have little effect on coronary circulation; however, in the case of the LM or LAD originating from the RCA or right coronary cusp and coursing posteriorly between the aorta and pulmonary artery, there is an associated increased mortality, usually secondary to arrhythmias and ischemia.

Angiographic Projections

When performing angiography of the coronary circulation, it is critical to obtain multiple views of each vessel in various orthogonal planes to define all the segments fully and clearly. Methodical, comprehensive angiography with orthogonal angulation prevents an operator missing a significant coronary lesion, which may be evident in only one plane but not another. By convention, all views are reported with left or right angulation first,

FIGURE 52-3 ■ Coronary angiography of the left (A) and right (B) coronary arteries in the right anterior oblique caudal (A) and left anterior oblique cranial (B) projections. *Diag*, Diagonal artery; *LAD*, left anterior descending artery; *LCX*, left circumflex artery; *LM*, left main artery; *OM*, obtuse marginal artery; *PDA*, posterior descending artery; *PLB*, posterolateral branch artery; *RCA*, right coronary artery.

FIGURE 52-4 ■ **A**, Nonselective angiogram of the left coronary sinus in an 81-year-old woman presenting with an acute inferior myocardial infarction and cardiogenic shock, demonstrating absence of coronary arteries arising from the left coronary cusp. **B**, Selective angiogram of the right coronary artery in the same patient revealing an anomalous origin of the left main coronary artery (LM) from the right coronary artery (RCA) and acute thrombotic occlusion of the proximal RCA. **C**, Angiography in the same patient after successful angioplasty of the RCA, now also demonstrating well-established collateral vessels to a severely diseased left circumflex coronary artery (LCX). **D**, Cardiac computed tomography angiogram three-dimensional reconstruction with virtual dissection of a similar anomalous LM arising from the RCA in a 21-year-old woman. **E**, Angiogram from a 54-year-old man with similar anatomy in the left anterior oblique cranial projection. The entire coronary system is visualized from a single ostium located at the right coronary sinus. The RCA and LM trunk arise together, and the LM divides into the left anterior descending (LAD) and LCX branches. *RI*, Ramus intermedius coronary artery.

followed by the degree of cranial or caudal angulation. For example, a 30/25 left anterior oblique (LAO)/cranial view represents 30 degrees of LAO angulation with 25 degrees of cranial angulation.

All major coronary arteries lie in one of two planes: the interventricular septum or the atrioventricular groove (Fig. 52-5). Standard angiographic projections are designed to display the coronary anatomy in profile in these planes. For example, the right PDA in its course along the interventricular septum and the inferior wall is best seen with the interventricular septum in its longest profile—the right anterior oblique (RAO) projection. On the other hand the LCX, which courses along the AV groove, is best visualized in the anteroposterior (AP) or RAO caudal projection, looking at the AV groove in profile.

Left Main Coronary Artery

The LM coronary artery is best seen in a shallow LAO projection with slight caudal angulation to visualize its middle and distal segments optimally, and with cranial angulation to improve visualization of its proximal and ostial segments. Another helpful view is the steep LAO caudal (also called the *spider view*) which lays out the terminal left main bifurcation. Unfortunately, this last view is not helpful in the case of a horizontally positioned heart, in which situation a steep RAO caudal view is substituted.

Left Anterior Descending Coronary Artery

The LAD courses anterior and inferior to the LM, enters the interventricular groove, and then travels to the apex

FIGURE 52-5 ■ Representation of coronary anatomy in relationship to the interventricular and atrioventricular valve planes as seen in two views: right anterior oblique (RAO) and left anterior oblique (LAO). Coronary branches are as follows: *AcM*, Acute marginal; *CB*, conus branch; *CX*, circumflex; *D*, diagonal; *L Main*, left main; *LAD*, left anterior descending; *OM*, obtuse marginal; *PD*, posterior descending; *PL*, posterolateral left ventricular; *RCA*, right coronary; *RV*, right ventricular; *S*, septal; *SN*, sinus node. In Baim DS, Grossman W, editors: Grossman's cardiac catheterization, angiography, and intervention*, ed 6, Philadelphia, 2000, Lippincott Williams and Wilkins.)

of the heart. No single view adequately depicts the entire course of the LAD. The proximal LAD is best visualized in steep LAO projections with cranial angulation, whereas the middle and distal segments are better seen in LAO and RAO views with some caudal angulation. In some cases, when the proximal LAD is not well seen in standard views (e.g., with a horizontally oriented heart), a 30 RAO/30 cranial angle better lays out the proximal LAD and LM bifurcation.

The diagonal arteries, the major branches of the LAD, course off the LAD toward the lateral free wall of the left ventricle. The best view for most of the diagonal arteries, to include their origin and distal segments, is usually a steep LAO (50 degrees) with steep cranial (50 degrees) angulation. In some cases, there is only one diagonal branch off the LAD—sometimes referred to as a *twin LAD* given its large area of subtended myocardium.

Left Circumflex Coronary Artery

The LCX is best seen in caudal projections. The proximal portion of the LCX is usually imaged in the RAO caudal angulation, which also lays out the marginal arteries. An alternative view for the mid segment of the LCX and the marginal arteries is the steep LAO caudal (spider) view. In obese patients, however, this latter view can be challenging, because the x-ray has to penetrate extra tissue, resulting in a distorted, dark, or hazy image.

Right Coronary Artery

The RCA enters the anterior AV groove and courses distally. The proximal segment of the RCA is best seen in the flat LAO angulation. For optimal visualization of the ostium, a steep (50 degrees) LAO projection is preferred. The mid segment of the RCA is best seen in the LAO and flat RAO projections. The crux, or distal RCA, and the proximal portions of the right PDA and PLB arteries are best seen with an AP or slight LAO projection with 20 to 30 degrees of cranial angulation. Finally, the middle and distal segments of the right PDA are best visualized with a flat RAO projection.

Bypass Graft Angiography

Saphenous vein grafts (SVG) to the right and left coronary circulations are commonly sutured onto the anterior surface of the aorta, several centimeters from the sinus of Valsalva (Fig. 52-6). RCA grafts generally arise from the right anterior aorta, whereas left coronary artery grafts usually originate from the left anterior aorta. LAD grafts are conventionally placed below LCX grafts. In some cases, the surgeon can also place a ring at the origin of a graft to facilitate identification of its origin off of the aortic root in the event of future angiography. The optimal views for engaging and imaging bypass grafts are flat LAO and RAO projections, which lay out the grafts in their greatest profile. The distal (native) vessel beyond the anastomosis is best imaged with the addition of cranial or caudal angulation to define all of the vessel segments fully (cranial for the LAD and RCA and caudal for the LCX; see Fig. 52-6).

In recent decades, the internal mammary artery (IMA) has emerged as the conduit of choice for the LAD, and in some cases for the RCA, because of the high patency rates of this conduit.³⁷ During angiography, the IMA is cannulated after engagement of the subclavian artery with the coronary catheter and J wire. The catheter is advanced into the subclavian artery and cleared, the J wire is withdrawn, and gentle counterclockwise torque is applied until the catheter engages the origin of the left IMA (LIMA). Once the vessel is engaged, the catheter is gently torqued clockwise to remove any excess tension.³⁸ Selective cannulation of an IMA graft can be challenging from the femoral approach in patients with peripheral or subclavian tortuosity. In these cases, the ipsilateral radial artery approach may better facilitate selective IMA engagement. Typical views for optimal angiography of the LIMA are AP or slight RAO (0-20 degrees)/cranial (40 degrees) to visualize the proximal and mid segments of the graft, and steep flat LAO or lateral projections to reveal the anastomosis of the LIMA with the native LAD. The right IMA conduit is similarly engaged from the right subclavian artery. The views for the mid-segment, origin, and anastomosis of this graft are typically flat

LAO with some cranial angulation and steep AP cranial angulation, respectively.

LESION STRUCTURAL AND FUNCTIONAL ASSESSMENT

Catheter-based invasive modalities are of profound clinical importance in accurately assessing coronary anatomy and physiology.^{39,40} Although coronary angiography provides unsurpassed temporal and spatial resolution compared with noninvasive imaging,⁴¹ it is often confounded by diffuse reference vessel disease, lesion foreshortening, vessel angulation, vascular calcification, lesion eccentricity, vessel overlap, and contrast streaming.⁴² Because of these limitations, the addition of precise morphologic, histologic, and functional information to angiography-only assessment through the use of adjunctive technologies such as fractional flow reserve (FFR) and intravascular ultrasound (IVUS) is indispensable to tailoring the treatment of patients with known or suspected coronary disease.

Fractional Flow Reserve

Inducible myocardial ischemia during functional testing has crucial prognostic significance in determining whether to treat angiographically indeterminate coronary artery lesions (those with an angiographic stenosis of 40% to 70%).⁴³⁻⁴⁶ In real-world practice, however, fewer than half of all patients undergo noninvasive evaluations for myocardial ischemia before coronary angiography.^{43,44} Integrating coronary physiology in the cardiac catheterization laboratory, principally using FFR, provides critical objective and accurate data about the ischemic potential of specific lesions, beyond angiographic anatomic details, and correlates well with noninvasive ischemic stress testing results.^{40,47}

FFR is the ratio of maximal myocardial blood flow in the case of a diseased artery to maximal myocardial blood flow if that same artery were normal.⁴⁸ This ratio of two flows can be accurately derived from the measurement of two pressures, provided they are measured during maximal hyperemia. During the procedure, a 0.014-inch pressure sensor guidewire is advanced beyond a coronary

stenosis and under conditions of pharmacologically induced maximal hyperemia (typically with intravenous adenosine) distal pressure (Pd) is recorded and divided by guiding catheter pressure (Pa), where:

$$FFR = Pd / Pa$$

To assess serial lesions or diffuse CAD, the pressure wire can be pulled back steadily from the distal to proximal vessels during continuous hyperemia, possibly demonstrating either an abrupt change in distal pressure across a focal narrowing or the gradual pressure recovery of diffuse disease without focal obstructions.

FFR is not influenced by systemic hemodynamics or contractile state; it is lesion and vessel specific, takes into account the contribution of collateral circulation, relates stenosis severity to the mass of subtended myocardium, and is highly reproducible.^{47,49} FFR also has a well-defined and validated cutoff value. Coronary stenoses with an

FFR < 0.75 almost uniformly induce myocardial ischemia, whereas stenoses with an FFR > 0.80 are rarely associated with exercise-induced ischemia, with a narrow “gray zone” for values between 0.75 and 0.80.^{41,49} In multiple studies, FFR has demonstrated clear utility in the assessment of angiographically indeterminate lesions,^{50,51} left main stenosis,^{52,53} multivessel disease,^{54,55} sequential stenoses (Fig. 52-7),⁵⁶ diffuse disease,⁵⁷ and bifurcation lesions.⁵⁸

In the setting of multivessel disease, FFR can be used to optimize both percutaneous and surgical revascularization outcomes. In the Fractional Flow Reserve Versus Angiography for Multivessel Disease (FAME) trial, FFR was used to guide multivessel percutaneous coronary intervention (PCI). A physiologically based approach with PCI of lesions with FFR ≤ 0.80 resulted in fewer stents, lower treatment costs, and fewer major adverse cardiac events at 2 years, compared with angiographically guided PCI.⁵⁴ In patients referred for coronary artery

FIGURE 52-7 ■ **A**, Schematic illustrating method of measuring fractional flow reserve (FFR). **B**, Angiogram of a 54-year-old man with serial angiographically intermediate stenoses of the left anterior descending coronary artery (LAD). FFR at dashed line (**C**) was 0.73, denoting a hemodynamically significant stenosis (star) of the mid LAD. Pullback gradient to the dotted line (**D**) demonstrated an FFR value of 0.83, indicating that the stenosis of the proximal LAD (asterisk) was not hemodynamically significant. After this FFR evaluation, only the mid-LAD lesion was stented. Postintervention FFR of the LAD beyond the stented segment was normal (>0.90) (not shown). LM, left main.

bypass grafting that have intermediate stenoses by angiography, a strategy of FFR-guided grafting with deferral of surgical revascularization of lesions with FFR > 0.80 has also been evaluated. Compared with angiographically guided grafting, patients with FFR-guided coronary artery bypass grafting had fewer anastomoses and lower rates of on-pump surgery. Clinical outcomes at 3 years showed similar rates of major adverse cardiac events and lower rates of angina in the FFR-guided group.⁵⁹

Intravascular Ultrasound

Intravascular ultrasound is a catheter-based pullback technique that provides invasive cross-sectional tomographic imaging. The clinical applications of IVUS are numerous and include assessment of plaque volume, stenosis severity, transplant vasculopathy, guidance of coronary stenting, and management of in-stent restenosis. With its excellent imaging quality and spatial resolution, IVUS (Fig. 52-8) provides complementary diagnostic information to traditional angiography and can differentiate atherosclerosis,⁴² coronary dissection,^{60,61} vasospasm,⁶² thrombosis, myocardial bridging,⁶³ fibromuscular dysplasia,⁶⁴ calcification,⁶⁵⁻⁶⁷ and stress cardiomyopathy.^{68,69}

Although IVUS cannot directly estimate the functional significance of coronary stenoses, strong correlations have been observed between IVUS-measured minimal luminal area and inducible ischemia as determined by myocardial perfusion imaging, coronary flow reserve, and FFR.⁷⁰ IVUS is particularly useful in the left main coronary artery segment, which has the greatest amount of interobserver variability when assessed by angiography alone,⁷¹ and has been used widely and successfully to identify patients at low risk for adverse events with deferred revascularization.⁷² Generally accepted criteria for deferral of revascularization in moderate left main disease include an IVUS-derived minimal luminal diameter >3.0 mm or a minimal lumen area >6.0 mm².^{73,74}

Additional modern IVUS modalities such as virtual histology IVUS allow for improved characterization of plaque burden and composition, correlate well with actual histology, and may provide incremental additional prognostic information.^{75,76} Finally, a newer light-based intravascular imaging modality, optical coherence tomography has even better near-field resolution compared with IVUS, thereby permitting better assessment of luminal area, measurement of neointimal volume, determination of patterns of proliferation, and quantification of endothelialization.⁶⁷

HEMODYNAMIC EVALUATION

Principles

Hemodynamic assessments performed alongside coronary angiography are an integral part of cardiac catheterization. The advent of procedures such as balloon valvuloplasty, percutaneous valve implantation, and septal ablation have revived interest in structural heart disease and comprehensive hemodynamic assessment

in the cardiac catheterization laboratory.⁷⁷ At any moment, hemodynamic values reflect the complex interaction between various dynamic processes: CAD, left ventricular function, systemic metabolic needs, and systemic and pulmonary pressures.⁷⁸ Hemodynamic measurements (vessel or ventricular pressures), measurement of cardiac output, and the evaluation of shunts are an essential aspect of diagnostic coronary evaluation. From a technical aspect, all pressures should be measured with a transducer that will allow direct real-time measurements after establishing a zero-reference, which is usually accepted as the mid-chest level in the AP direction.

Right Heart Catheterization

The measurement of right heart (RH) pressures and oxygen saturations is a simple and accurate method of assessing real-time cardiovascular conditions. Cardiac output (CO) is the flow of blood from the heart to the body and is reported in liters per minute; this can be standardized for a patient's size by dividing by the patient's body surface area (BSA) to arrive at the cardiac index (CI), which is reported in liters per minute per meters squared.

During RH catheterization (RHC), oxygen saturations should be obtained from the superior vena cava (SVC), inferior vena cava (IVC), right atrium, right ventricle, pulmonary artery (PA), and pulmonary capillary wedge pressure (PCWP) positions. When obtained with simultaneous arterial saturation measurements, the CO or CI can be calculated, and shunts can be quantified if present.

Pressure tracings are obtained at each level of advancement of the RH catheter. Normal values for the RH and systemic arterial (LV) pressures are shown in Figure 52-9. Since the introduction of the balloon-tipped RH catheter by William Ganz and Jeremy Swan in 1970,⁷⁹ RHC has become a common and essential component of cardiac catheterization.

Pressure Waveforms

Right Atrium

The *a* wave occurs during atrial systole, which follows the *P* wave on the surface electrocardiogram (ECG). During atrial diastole, there is a decline in the pressure waveform, which corresponds to the *x* descent. In the ventricle, as systole begins, the *x* descent may be interrupted by movement of the tricuspid valve, termed the *c* wave, with the remainder of the *x* descent called *x'*. As ventricular systole progresses and forward flow occurs, the tricuspid valve closes, and right atrial filling results in the *v* wave. Ultimately, ventricular relaxation occurs, the tricuspid valve opens, and atrial pressure falls as blood flows from the right atrium to the right ventricle. This corresponds to the *y* descent.

Right Ventricle

Right ventricular pressure rises with ventricular systole. As diastole commences, the pulmonic valve closes and a

FIGURE 52-8 ■ **A**, Coronary angiography in a 42-year-old postpartum woman in the right anterior oblique caudal projection demonstrating severe spontaneous coronary artery dissection of the left anterior descending coronary artery (LAD). The *dashed line in red* represents the course of the left anterior descending artery. *Dotted lines in white* mark the locations of the accompanying intravascular ultrasound (IVUS) images of the normal left circumflex coronary artery (LCX) and the dissected LAD. **B**, Intravascular ultrasound of the normal LCX. Green dotted line outlines the adventitia; yellow dotted line outlines the intima. **C**, Intravascular ultrasound of the dissected proximal LAD demonstrating large intramural hematoma (*asterisk*) between the intimal (*yellow dotted line*) and the adventitial (*green dotted line*) vessel layers, compressing the vessel lumen. LM, Left main.

rapid decline in pressure ensues. After the tricuspid valve opens, there is rapid filling of the ventricle and a slow increase in its pressure. With atrial systole, the final pressure recorded is the end-diastolic pressure.

Pulmonary Artery

In the pulmonary artery, after the pulmonic valve opens in ventricular systole, there is a rise in the systolic pressure. As diastole commences, the pressure declines. With closure of the pulmonic valve, the diastolic pressure plateaus at a higher level than in the ventricle. Usually, the

diastolic pressure of the PA correlates closely with the left atrial (LA) pressure and PCWP.

Pulmonary Capillary Wedge Pressure

A wedge pressure is obtained using a balloon-tipped catheter “wedged” into a distal pulmonary artery; this transduces pressure from the downstream circulation (i.e., the left atrium).⁸⁰ This simple maneuver allows for indirect measure of LA pressures without the need for trans-septal puncture. Numerous studies have validated PCWP as a surrogate for LA pressure in the

FIGURE 52-9 ■ Normal cardiac chamber pressures and pressure tracings. **A**, Normal right atrial (RA) waveform. Waves: *a*, from atrial systole; *v*, from ventricular systole. Arrows indicate the timing of the *a* and *v* waves relative to the electrocardiogram. **B**, Normal right ventricular (RV) waveform. **C**, Illustration of the cardiac chambers and great vessels with normal pressure ranges in mm Hg. **D**, Normal pulmonary artery (PA) waveform with the arrow depicting the aortic valve closure. **E**, Normal pulmonary capillary wedge pressure (PCWP) waveform showing the timing of the *a* and *v* waves relative to the electrocardiogram. evaluation of mitral stenosis and other hemodynamic conditions.⁸¹

Systemic Arterial Pressure

The arterial pressure waveform begins with LV systole. Once the aortic valve opens, systolic pressure rises precipitously. As ventricular diastole begins and pressures fall, the aortic valve closes and the aortic pressure declines. An interruption in the pressure tracing corresponds to the aortic valve closure, a phenomenon identified by the

dicotic notch on the arterial waveform. Depending on the patency of the aortic valve and the compliance of the aorta, the usual pulse pressure is 45 to 50 mm Hg. In noncompliant aortic systems, such as in older subjects with calcified vessels or patients with significant aortic regurgitation, there is often a widened pulse pressure.

Cardiac Output

Cardiac output, the amount of blood delivered to provide oxygen, glucose, and nutrients to the body, is expressed

in liters per minute. This measurement can be obtained through several methods, such as the Fick, thermodilution, or dye methods.^{82,83} The Fick method is most commonly used in the cardiac catheterization laboratory. It assumes that the rate at which oxygen is consumed is a function of both the rate of blood flow and the rate of oxygen loading by the red blood cells. By measuring the difference in the oxygen content in the arterial and mixed venous circulations (A-V O₂ difference) and the oxygen consumption, CO can be calculated as follows:

$$\text{CO (L/min)} = \text{O}_2 \text{ consumption (mL/min/m}^2\text{)} \div \text{A-V O}_2 \text{ difference} \times \text{BSA}$$

Normal oxygen consumption indices ranges from 110 to 150 mL/min/m² (see Fig. 52-3). To standardize calculations, oxygen consumption index is commonly assumed to be 125 mL/min/m² (or 110 mL/min/m² for older women). This index is then multiplied by the subject's BSA in meters squared to arrive at the oxygen consumption, and thus the cardiac output. If this value is not multiplied by the BSA, the cardiac index results instead.

A more reliable way to determine O₂ consumption is by direct measurement. This measurement can be accomplished using the Douglas bag, in which the oxygen content of expired air is compared with the oxygen content in the ambient air, and oxygen consumption is calculated. O₂ consumption can also be determined using a metabolic rate meter.⁸⁴ With this method, the patient breathes into a container in which O₂ and CO₂ sensors measure the expired content of O₂ and CO₂, and the oxygen consumption is calculated accordingly. To calculate the A-V O₂ difference, one needs the arterial oxygen

saturation (sat), the mixed venous oxygen saturation, and the hemoglobin (Hgb) concentration:

$$\begin{aligned} \text{A-V O}_2 \text{ difference} &= P_A (\% \text{ sat}) - P_a (\% \text{ sat}) \\ &\times (\text{Hgb in g/dL}) \\ &\times (1.36 \text{ mL O}_2/\text{g Hgb}), \end{aligned}$$

where P_A is the oxygen saturation in the peripheral arterial circulation (assumed to be the same as in the LV or pulmonary vein), P_a is the oxygen saturation in the pulmonary artery, Hgb is the hemoglobin concentration in the blood, and 1.36 is the correction factor for the capacity of fully saturated hemoglobin to carry oxygen.

SHUNTS

When blood flow crosses from one cardiac chamber to another without traversing a valve, a shunt is present. Evaluation, detection, and localization of these intracardiac shunts are integral parts of diagnostic coronary and RH catheterization.^{77,85}

Left-to-Right Shunts

The typical left-to-right shunt seen in the catheterization laboratory is an atrial septal defect (ASD). Other causes of left-to-right shunting are patent foramen ovale (PFO), ventricular septal defect (VSD; Fig. 52-10), and patent ductus arteriosus. In each of these conditions, there is an increase in oxygen saturation at a different level of the RHC. In the case of an ASD, the increase occurs in the right atrium; for a VSD, it is in the right ventricle; for a

FIGURE 52-10 ■ Ventricular septal defect (VSD; yellow asterisk) with opacification of the right ventricle (RV) via the VSD during left ventriculography from right (A) and left (B) anterior oblique projections. Dashed red lines outline the left ventricle (LV); dashed white lines outline the RV.

patent ductus arteriosus, it is in the PA. The key to understanding and quantifying these shunts is determining where the most-mixed venous sample is obtained. In the case of an ASD, it is a combination of the SVC and the IVC saturations; for a VSD it is the right atrium; for a patent ductus arteriosus, it is the right ventricle.

In a shunt evaluation, oximetry is the method by which the right heart chambers or vessels are evaluated. Early work by Dexter and colleagues⁸⁶ defined the standard range for maximal changes in oxygen saturation while progressing from one RH chamber to another. In general, a maximal change of 8% from the SVC to the PA is considered sufficient to prompt further evaluation to identify the presence and extent of an intracardiac shunt.

If a shunt is suspected, oximetry is performed to identify and then quantify the shunt. Pulmonary and systemic blood flows are first calculated. Next, the magnitude of the left-to-right shunt is derived. Pulmonary blood flow (Q_p) is calculated with the formula:

$$Q_p = \text{O}_2 \text{ consumption (mL/min)} \div [(P_V\text{O}_2) - (P_A\text{O}_2)]$$

and systemic blood flow (Q_s) is calculated with the formula:

$$Q_s = \text{O}_2 \text{ consumption (mL/min)} \div [(S_A\text{O}_2) - (M_V\text{O}_2)],$$

where $M_V\text{O}_2$ denotes the mixed venous oxygen concentration.

The Q_p/Q_s is the ratio of the relative blood flows in the pulmonary and systemic circulations, which can be reduced to:

$$Q_p / Q_s = (S_A\text{O}_2) - (M_V\text{O}_2) \div [(P_V\text{O}_2) - (P_A\text{O}_2)]$$

As mentioned previously, $M_V\text{O}_2$ is a value of the average oxygen concentration from the right atrium for a VSD and from the right ventricle for a patent ductus arteriosus. For an ASD, this value is derived from the Flamm equation,⁴¹ where:

$$M_V\text{O}_2 = [3 (\text{SVC}) + 1 (\text{IVC})] \div 4$$

A Q_p/Q_s value greater than 2.0 is considered abnormal, and it warrants consideration of surgical correction or percutaneous closure of a cardiac shunt. Values between 1.5 and 2.0 are intermediate, for which surgical or percutaneous closure can be pursued if procedural risk is low or if symptoms (e.g., cryptogenic stroke in the case of an ASD) or secondary structural and functional cardiac changes are present. A ratio of less than 1.0 suggests a right-to-left shunt.

Right-to-Left Shunts

A significant right-to-left shunt is generally detected early, without catheterization, as the patient typically manifests cyanosis or arterial hypoxemia. The oximetric evidence is a Q_p/Q_s of less than 1.0. A ratio of less than 0.7 is considered critical, and less than 0.3 is not compatible with life.

Regardless of the cause, the basis for evaluation of the site of a right-to-left shunt may be analyzed by obtaining PV, LA, LV, and aortic saturations. When the shunt is extra-anatomic from the pulmonary circulation, the site of stepdown is the site of the shunt. For example, if the stepdown occurs in the LV, a VSD is present. This evaluation requires direct sampling within the left atrium via trans-septal puncture.

Bidirectional Shunts

If there is evidence of both left-to-right and right-to-left shunting, a formula comparing the effective blood flow (Q_{eff}) is used. This flow rate is the hypothetical flow in the absence of any shunting:

$$Q_{\text{eff}} = \text{O}_2 \text{ consumption (mL/min)} \div [(P_V\text{O}_2) - (M_V\text{O}_2)]$$

Then the left-to-right and right-to-left shunts can be calculated as $Q_p - Q_{\text{eff}}$ and $Q_{\text{eff}} - Q_s$, respectively.

VASCULAR RESISTANCE

Vascular resistance is calculated by dividing the pressure gradient across the vascular bed in question by the blood flow through that same bed. In essence, there are two major vascular beds: systemic and pulmonary. For systemic vascular resistance (SVR):

$$\text{SVR} = (\text{Mean arterial pressure} - \text{Right atrial pressure}) \div \text{CO}$$

For pulmonary vascular resistance (PVR):

$$\text{PVR} = (\text{PA pressure} - \text{PCWP [LA pressure]}) \div \text{CO}$$

Normal values for the SVR and PVR are listed in [Table 52-1](#). A high SVR is seen in patients with systemic hypertension, hypovolemia, significant blood loss, and CHF, whereas a low SVR is seen with high fevers, sepsis, thyrotoxicosis, or arteriovenous fistulae.

VALVULAR HEART DISEASE

The assessment of valvular abnormalities is an integral part of any catheterization. During routine right and left heart catheterization, diagnostic information can be derived for all four valves in the heart. The principal valvular anomalies that require interrogation and potential surgical or catheter-based repair are typically: aortic stenosis (AS), aortic regurgitation (AR), mitral stenosis (MS), mitral regurgitation (MR), pulmonic stenosis, and in some cases, tricuspid regurgitation.

Aortic Stenosis

Hemodynamically significant AS occurs secondary to either primary valve pathology (congenital bicuspid aortic valve) or to valve degeneration (senile calcific AS).⁸⁷⁻⁸⁹ Patients referred for catheterization for evaluation of AS

TABLE 52-1 Normal Values

Reference Point	Value
Oxygen consumption index (mL/min/m ²)	110-150
A-V O ₂ difference (mL/L)	30-50
Cardiac output	2.5-4.2
Cardiac index	2.0-3.0
Resistances	
Pulmonary vascular resistance	20-130
Systemic vascular resistance	700-1600

A-V O₂ difference, Arterial and mixed venous circulations.

generally have one of the following indications for the procedure: syncope, angina, or LV systolic dysfunction. Catheterization is recommended for hemodynamic assessment of the severity of AS if the results of noninvasive tests are equivocal or if there is discordance between the clinical assessment of severity and the results of noninvasive tests.⁹⁰⁻⁹²

To determine the significance of AS, simultaneous measurements of pressure across the aortic valve must be performed. A catheter is passed into the LV cavity, and the systolic pressure in the LV cavity is compared with a simultaneous pressure measurement in the ascending aorta, with either a dual-lumen (preaortic valve and post-aortic valve) catheter across the aortic valve or the use of two separate catheters. Use of the femoral artery sheath pressure is not recommended as a substitute for direct aortic measurements because of pressure augmentation in the periphery.

Traversing the aortic valve in a retrograde fashion can be challenging in patients with severe AS with small aortic valve openings and deformed and calcified valve apparatus. Although one can attempt retrograde crossing of the aortic valve with a pigtail catheter alone, more commonly the valve is probed with a straight wire extended from the tip while changing the orientation of the catheter for serial probing of different regions of the valve orifice. If the pigtail catheter does not provide adequate orientation for crossing, as is often the case, then a JR4 or AL1 catheter can improve the orientation of the wire and more easily allow passage into the LV.

Once the LV is entered, simultaneous pressures should be measured, along with a simultaneous CO. A simultaneous PCWP tracing via the RHC is also obtained at this time to evaluate any mitral valve gradient. Once the CO is determined, the aortic valve area can be calculated using the Gorlin equation,⁹³ as follows:

$$\text{Aortic valve area (cm}^2\text{)} = \frac{\text{CO}}{[(\text{DFP or SEP}) \times \text{HR} \times C \times \sqrt{P}]},$$

where *DFP* or *SEP* is the diastolic filling period or systolic ejection period, *HR* is heart rate in beats per minute, *C* is an empirical constant (44.3 for aortic and tricuspid valves, and 37.7 for the mitral valve), and *P* is the pressure gradient.

In the Gorlin equation, heart rate and systolic ejection periods are generally similar in most patients. Therefore, an alternative (and simpler) equation, the Hakki formula,

is commonly used.⁹⁴ With this equation, the aortic valve area is estimated by dividing *CO* by the square root of the peak-to-peak gradient (*P*) across the aortic valve:

$$\text{Valve area} = \text{CO} \sqrt{P}$$

Aortic stenosis is considered severe when the valve area is less than 1.0 cm², or critical when the valve area is less than 0.7 cm². Indications for aortic valve replacement under such conditions include symptomatic severe AS; severe AS in the setting of coronary artery bypass, aortic root, or other valvular surgery; and severe AS in the setting of a depressed left ventricular ejection (<50%).^{90,92} Aortic valve replacement is also considered reasonable for patients with moderate AS undergoing other planned cardiac or aortic surgery. If aortic valve replacement is contraindicated or carries unacceptable surgical risk because of other medical comorbidities, a temporizing aortic valvuloplasty or more durable transcatheter valve implantation procedure can be considered instead.

Balloon aortic valvuloplasty (BAV) was first developed as a technique to treat aortic stenosis in 1985.⁹⁵ Originally conceived as an alternative to surgical valve replacement, interest waned because the long-term outcomes from aortic valve dilation were poor, with early recurrence of stenosis. BAV was thus relegated to a temporizing role used in palliation or bridge to surgery.⁹⁶ The recent advent of transcatheter aortic valve implantation (TAVI) has brought with it new indications for BAV, which is increasingly being used as a therapeutic trial to assess the potential benefit of definitive aortic valve treatment in patients where alternate assessments are inconclusive, or alternatively as a bridge to TAVI.⁹⁷⁻¹⁰¹

Aortic Regurgitation

Aortic regurgitation (AI) is the result of an incompetent aortic valve. With AI, blood enters the LV cavity in diastole in a retrograde fashion across the aortic valve. The consequence of regurgitation is an increased demand on the LV, which must work harder to maintain adequate forward flow. The magnitude of the regurgitant volume depends on the size of the regurgitant orifice of the valve and on the pressure difference between the aorta and LV in diastole. The principal causes of AR are primary diseases of the valve (rheumatic or endocarditis) and of the aortic root (aneurysm, syphilis, ankylosing spondylitis).¹⁰²⁻¹⁰⁵

Chronic AR is identified by a widened pulse pressure on noninvasive measurements and classic physical examination findings: Quincke pulses (nailbed capillary pulsations), Duroziez sign (systolic murmur over the femoral artery during proximal compression and diastolic murmur during distal compression), Corrigan pulse (water-hammer pulsation with early rise and collapse), Austin-Flint murmur (early closure of the mitral valve from AR, simulating MS), or de Musset sign (head bobbing with each cardiac cycle).

Preoperative evaluation of patients with chronic AR includes coronary angiography and evaluation of LV function. If the patient is mildly symptomatic or

symptomatic with exercise testing, or if there is any deterioration of LV function, aortic valve replacement is warranted.^{90,91,103} Overall, the goal is replacement of the valve before deterioration of LV function.

Mitral Stenosis

Mitral stenosis is almost invariably caused by rheumatic heart disease. The fusion of the mitral apparatus is from the commissure at the cusps, is subvalvular at the cusps, or is a combination of the two.^{106,107} In adults, the normal valve area ranges between 4 and 6 cm². When the valve area is less than 2 cm², mitral stenosis is considered mild; less than 1 cm² is considered critical mitral stenosis. Because the hemodynamic result of chronic mitral stenosis is elevated pulmonary pressure, the typical feature of severe and critical mitral stenosis is dyspnea with exertion.

Determining the gradient across the mitral valve can be accomplished in two ways. LA pressure can be measured directly, through a trans-septal puncture into the left atrium from the right atrium. Although this is the most accurate method of determining the LA pressure, it carries inherent risks, such as aortic puncture or PA puncture. A well-validated and lower-risk approach is to obtain a PCWP via right heart catheterization simultaneously with LV pressure measurements. With either method, reliable mitral valve gradients and valve area measurements can be determined. Along with anatomic valve data, this information helps to guide the decision to perform either valvuloplasty or surgical valve replacement.

Procedurally, access is obtained in both the femoral artery and femoral vein. An RHC is performed, and a “confirmed” PCWP is obtained. Confirming the PCWP position by measuring oxygen saturation ensures the validity of the pulmonary vein samples obtained for the valve area calculation. A pigtail catheter is next placed into the LV cavity, and simultaneous tracings of LV pressure and PCWP are obtained. A normal gradient (<5 mm Hg) at catheterization can be further evaluated by exposing the patient to hemodynamic stress, via exercise, medications, or atrial pacing, to increase the atrial gradient. Once the maximal gradient is confirmed by these methods, and the diastolic filling periods and CO are obtained, the valve area can be calculated with the Gorlin equation. As with AS, the Hakki formula⁹⁴ (if calculated under adequate conditions of heart rate and CO) can also be used to approximate the mitral valve area by dividing the CO by the square root of the transvalvular gradient.

Mitral Regurgitation

Mitral regurgitation can be a consequence of disruption of the mitral leaflets, annulus, or subvalvular apparatus, including the chordae and papillary musculature.¹⁰⁸⁻¹¹⁰ Mitral leaflet abnormalities generally result from rheumatic heart disease, chronic mitral valve prolapse, or bacterial endocarditis. Other causes include systemic diseases such as systemic lupus erythematosus. When the mitral annulus becomes dilated as a secondary consequence of LV dilation, the annulus may no longer permit coaptation of the mitral cusps, with MR as the result. Furthermore,

if the annulus becomes calcified, the ability to constrict with ventricular contraction is impaired, and MR may again result. Lastly, chordal and subchordal structures (papillary muscles) may be congenitally short, long, or fibrotic. They can rupture because of ischemic or infectious myonecrosis, or may become dysfunctional because of ischemia. Any of these clinical scenarios can prevent optimal tethering of the valvular apparatus in systole, resulting in MR.

Ischemic MR is a special case of significant mitral regurgitation.^{111,112} The posterior papillary musculature has a single blood supply (usually via the LCX). Following an acute coronary syndrome involving the obtuse marginal circulation of the LCX, potentially significant and acute MR, often with resultant CHF, can ensue.

In the cardiac catheterization laboratory, significant MR can be assessed with left ventriculography in addition to right heart catheterization. In the RAO projection, the left ventricle and left atrium are both seen in profile, permitting assessment and quantification of MR. Mild MR (1+) promptly clears before the next cardiac cycle; mild-to-moderate MR (2+) clears after the next cycle and does not opacify the left atrium to the same degree as the left ventricle; moderate-to-severe MR (3+) does not clear with subsequent cardiac cycles and opacifies the atrium as much as the left ventricle; and severe MR (4+) does not clear with subsequent cardiac cycles and opacifies the left atrium more than the left ventricle.

Recently, percutaneous clip repair has emerged as a novel endovascular alternative to surgical valve repair.^{113,114} Other percutaneous methods, such as direct and indirect mitral annuloplasty and transcatheter mitral valve replacement, are currently under investigation.¹¹⁵ Overall, clinical indications for surgical or endovascular repair or replacement are based on symptoms, hemodynamic assessment, left ventricular size, and other resultant comorbidities (such as atrial fibrillation).^{90,92}

PERICARDIAL DISEASE

The pericardium forms a cavity that is held firmly in place in the chest by attachments to the sternum, vertebral bodies, and the diaphragm, despite changes in body position.⁷⁰ The pericardium has two layers: an inner (visceral) layer intimately associated with the surface of the heart, and an outer (parietal) layer that is the continuation of the visceral pericardium as it reflects on itself. The parietal pericardium is fibrous, whereas the visceral pericardium is smooth and composed of a single layer of mesothelial cells. Within the pericardial space in a normal state is approximately 50 mL of clear, ultrafiltrate fluid that acts as a lubricant to reduce friction between the heart and the surrounding pericardium.¹¹⁶⁻¹¹⁹

Normal pericardial pressures are zero or negative, and thus have only a small effect on cardiac distending pressures. Several pericardial abnormalities, such as acute pericarditis and pericardial effusion, with or without cardiac tamponade, and constrictive pericarditis, can be evaluated effectively in the cardiac catheterization laboratory.

Pericarditis

Acute pericarditis is caused by inflammation of the pericardium that results in chest pain, possibly a pericardial friction rub, and ECG abnormalities.¹²⁰ Acute pericarditis can be infectious, idiopathic, uremic, neoplastic, or secondary to trauma. The principal indication for evaluating a patient with pericarditis in the catheterization laboratory is the presence of an effusion requiring pericardial drainage or sampling.

ECG signs of acute pericarditis and pericardial effusion include nonspecific ST-segment abnormalities, diffuse ST elevation up to 1 to 2 mm, and PR-segment depression. Because the heart can swing with each cardiac cycle within the fluid space of the effusion, electrical alternans may also be observed in the presence of a large effusion. Once suggested, a pericardial effusion can be readily confirmed with echocardiography.

Cardiac Tamponade

One of the consequences of a large or acute pericardial effusion is cardiac tamponade. In tamponade, an increase in intrapericardial pressure leads to an elevation of intracardiac pressures (with ultimate equalization of chamber pressures), abnormalities of the jugular venous pressures, progressive limitation of ventricular diastolic filling, and finally a reduction of stroke volume and CO.¹²¹ Given this constellation of hemodynamic effects, the clinical findings of a patient with impending or fulminant tamponade are tachycardia, a large pulsus paradoxus, and abnormalities of the jugular venous pulsations. If clinical signs or echocardiographic findings suggest tamponade, a pericardial drain should be placed immediately (Fig. 52-11).

Historically, pericardiocentesis was performed in a blinded or ECG-guided fashion, usually from the subxiphoid approach. Currently, however, pericardiocentesis

is typically performed with echocardiographic or fluoroscopic guidance, or both. In the catheterization laboratory, the pericardial space is usually approached from left of the subxiphoid process, with the needle directed toward the patient's left shoulder.¹²² Often an RHC is performed concurrently via the internal jugular vein, femoral vein, or brachial vein to evaluate PCWP and right atrial pressures. The arterial system is also accessed, via the right femoral artery or right radial artery. Right atrial (central venous) pressures should demonstrate blunted x and prominent y descents. Hypotension and often pulsus paradoxus are observed in the arterial tracing.

Once the pericardial space is entered, confirmation of pericardial position is performed with injection of agitated saline under echocardiography or diluted contrast under fluoroscopy. With the needle in the pericardial space, the pressure is transduced and compared with that of the catheter in the right atrium. If tamponade is present, the pressures should be similar and track each other. A J-tipped wire is then advanced into the pericardial space. A dilator is advanced over this wire, and ultimately a multilumen pigtail catheter is placed. At this time, fluid samples are sent for laboratory evaluation (electrolytes, pH, cultures, hematocrit). Aspiration of the effusion follows, with intermittent hemodynamic assessments and removal of as much fluid as possible to promote reapposition of the parietal and visceral pericardial layers. As the effusion is drained, the pericardial pressure should return to zero or negative, with a resultant decline in right atrial pressure. The drain should be left in place until the drainage falls to less than 25 mL over 24 hours and repeated echocardiography reveals no significant residual effusion.

Constriction-Restriction

Constrictive pericarditis and restrictive cardiomyopathy share similar hemodynamic features and are difficult to

FIGURE 52-11 ■ **A**, Echocardiogram in the parasternal long axis view demonstrating a large circumferential pericardial effusion (*star*). **B**, Hemodynamic tracings demonstrate hypotension and pulsus paradoxus (asterisk) in the femoral artery (FA) pressure tracing and loss of the y descent in the right atrial (RA) pressure tracing (*top*). After pericardiocentesis, there is an increase in arterial pressure and return of the y descent in the RA pressure tracing (*bottom*). **C**, Pericardial drain (*arrow*) in the pericardial space. LV, Left ventricle; RV, right ventricle. (B, From Sorajja P: Invasive hemodynamics of constrictive pericarditis, restrictive cardiomyopathy, and cardiac tamponade. *Cardiol Clin* 29:191–199, 2011.)

differentiate. Thus, the diagnosis can remain equivocal even after extensive noninvasive and invasive evaluations.^{121,123,124} Constriction most commonly follows acute pericarditis with fibrin deposition and scarring of the pericardium, ultimately leading to uniform restriction of diastolic filling.¹²⁵

As in tamponade, there is an elevation and equalization of the diastolic pressure in all four cardiac chambers. The central venous pressure shows a prominent *x* and *y* descent, frequently appearing as a “W” waveform. The right and left ventricular tracings reveal diastolic equalization with the classic “dip and plateau” of ventricular filling: there is rapid ventricular filling in early diastole (dip) and slow or negligible filling in late diastole (plateau). It is important to remember that if ventricular filling is low, such as in hypovolemia, these classic patterns might not be observed. In this instance, a volume load will raise the right atrial pressure and facilitate identification of constrictive pericarditis. Another hemodynamic effect of a uniform constriction to cardiac filling is the absence of transmission of intrathoracic pressures to the pericardium and heart chambers, which results in Kussmaul sign: increases in systemic venous and right atrial pressures with inspiration.¹²⁶

CONCLUSION

Despite significant advances in noninvasive imaging modalities and diagnostic methods, invasive cardiac testing, to include coronary angiography, right and left heart catheterization, and morphologic and physiologic lesion assessment with IVUS and FFR, remain critical components of a complete and thorough diagnostic or preprocedural (whether percutaneous or surgical) cardiac evaluation.

Coronary Artery Imaging

THE FUTURE ROLE OF CMR AND CCT

Cardiovascular magnetic resonance (CMR) and cardiovascular computed tomography (CCT) are increasingly used in the diagnosis and management of cardiovascular disease.^{1,2} Both of these advanced imaging modalities have overcome similar challenges posed by cardiac and respiratory motion and have met the demand for high temporal and spatial resolution to enable noninvasive imaging to aid in the diagnosis and management of a variety of cardiovascular disorders. In addition, CMR and CCT have unique capabilities that permit great flexibility, precision, and reproducibility in the acquisition and display of anatomic and functional data that are useful for surgical diagnosis, planning, and subsequent monitoring.

IMAGING PRINCIPLES AND APPROACHES

CMR imaging is performed using static and dynamic magnetic fields and does not use any ionizing radiation.

Images are generated from induced radiofrequency signals arising from water and fat protons in the body. Differences in proton density, magnetic relaxation times (longitudinal relaxation time [T_1] or transverse relaxation time [T_2]), blood flow, and other parameters produce intrinsic signal contrast among tissues. CMR approaches can be broadly classified into spin-echo (black blood) and gradient-echo (bright blood) and the derived balanced steady-state free-precession (b-SSFP) sequences for cine acquisitions, often modified with prepulses. Spin-echo imaging is particularly useful for defining anatomic structure and tissue characterization (e.g., fat replacement or iron deposition). Gradient-echo techniques can produce single-shot (displaying a single phase during the cardiac cycle) or cine (displaying multiple phases at one level during the cardiac cycle) images, with an improved signal-to-noise ratio (SNR) using b-SSFP sequences. Cine images demonstrate motion of structures (such as cardiac chambers and valves) during the cardiac cycle, permitting qualitative and quantitative assessment of motion. Both spin-echo and gradient-echo CMR

techniques are flow-sensitive. Because of the inherent contrast between the blood pool and surrounding tissue, administration of an exogenous CMR contrast agent is not required for general evaluation of cardiac anatomy. Although the U.S. Food and Drug Administration approved it for angiography (e.g., contrast-enhanced magnetic resonance angiography [CE-MRA]), but not for cardiac applications, the administration of gadolinium chelates as extracellular magnetic resonance (MR)-specific intravenous contrast agent enables certain applications, such as first-pass assessment of myocardial perfusion and late gadolinium enhancement (LGE) for fibrosis and scar identification. Gadolinium induces T_1 shortening, which is detected as an increased signal in T_1 -weighted images, although the signal enhancement is not linearly related to contrast agent concentration. Diverse techniques are under development to quantify magnetization dynamics before and/or after gadolinium administration (T_1 mapping), allowing improved cardiac tissue characterization.³ Flow-velocity encoding (also known as *phase contrast*) is an additional CMR modality that enables volumetric quantitation of blood flow through arteries, veins, conduits, and valves. This method enables determination of regurgitant volumes and shunt flows.

CCT uses ionizing radiation to generate images based on the attenuation of the body's tissues. Today, CCT is typically performed using third-generation multislice scanners. These CCT units are arranged with the radiation tube opposite a series of detectors attached to a gantry that rapidly rotates as the patient is advanced through the scanner. The detector arrays typically obtain 64, dual-64, 256, or 320 axial slices during a single gantry rotation. Higher numbers of slices allow for greater coverage with each gantry rotation, allowing for shorter imaging times, less iodinated contrast, and potentially reduced radiation exposure. In the helical mode, data are acquired in a helical path as the patient is advanced through the scanner. The speed at which the patient is advanced through the scanner is called the *pitch*. A high pitch (faster speed) is associated with a lower radiation exposure, whereas a low pitch (slower speed) is associated with a higher spatial resolution, but also higher radiation exposure. Cardiac imaging is generally performed with a relatively low pitch. The radiation exposure can be reduced by electrocardiogram (ECG) dose modulation, which varies the intensity of radiation exposure during the cardiac cycle.

CHALLENGES OF CARDIAC IMAGING

CMR and CCT have faced similar challenges posed by cardiac and respiratory motion, and requirements for high temporal, spatial, and contrast resolution. The acquisition of most cardiac images requires electrocardiographic gating or triggering during a specific portion of the cardiac cycle with data acquired from successive heartbeats. Thus, imaging is usually best when performed in patients with a regular sinus rhythm. The duration of image acquisition with CCT is generally fewer than 10 to 15 seconds, allowing a single breath-

hold for suppression of respiratory motion. Although breath-holding is used for many CMR acquisitions, free breathing, navigator gating is often used for longer image acquisitions or in situations in which patients cannot sustain a breath-hold. Navigators are a CMR technique that identifies a "signal interface" such as that between the lung and the diaphragm. Most commonly, the dome of the right hemidiaphragm is used for this purpose. Real-time navigator data about the position of the lung/diaphragm interface can then be used for respiratory gating.

High temporal resolution is needed to take advantage of these gating techniques. CMR images can be acquired with a variable temporal resolution at the expense of increased acquisition time. Typical cine temporal resolutions of less than 40 ms are acquired. The temporal resolution of CCT is limited by gantry rotation speed, with typical gantry rotation speeds of 330 to 400 ms per rotation. The use of half-cycle reconstruction allows for an image to be acquired in one half-rotation, with an effective temporal resolution of 165 to 200 ms. Intravenous or oral β -blockers are typically administered for coronary artery CCT to prolong the period of diastasis during which the coronary artery can best be imaged. The temporal resolution of CCT can be improved to approximately 83 ms with dual-source technology, in which two sets of radiation tubes and detectors are mounted on the gantry. Each set acquires data over one quarter-rotation and the data are combined to form a single image. Multicycle reconstruction can also be used to improve the temporal resolution of CCT to approximately 40 ms by acquiring data for a single image over multiple cardiac cycles, but this is infrequently used because of the requirement for a very low pitch and a resultant very high radiation exposure.

The development of high spatial resolution has also been important for CMR and CCT, particularly for coronary artery imaging. Spatial resolution of CMR is also variable, but again at the expense of increased acquisition time and loss of SNR. The latter can be somewhat mitigated by imaging at higher field strengths (e.g., 3 T). Typical in-plane spatial resolutions of 1 to 2 mm are used with 3- to 8-mm slice thickness, whereas the spatial resolution of CCT has improved with the development of smaller detectors. Routine CCT generally has a higher spatial resolution compared with CMR, with CCT isotropic spatial resolution of 0.5 to 0.6 mm. Image contrast for CMR is created using specific imaging sequences and prepulses. The use of an exogenous contrast agent (e.g., gadolinium) is required for specific applications, as noted before. CCT does not have the inherent contrast between tissues of CMR. Thus, iodinated contrast is required for the vast majority of CCT imaging. The timing of iodinated contrast administration relative to image acquisition is critical, with imaging typically performed during passage of iodinated contrast in the ascending aorta and coronary arteries. The correct timing is determined by a small timing bolus or by automated detection of contrast appearance in the ascending or descending aorta. A similar process is used for CE-MRA of the aorta and pulmonary veins. LGE imaging also uses specific timing parameters but is overall less time-sensitive.

IMAGING COMPARISONS

The advantages and limitations of CMR and CCT complement those of other imaging techniques such as echocardiography, fluoroscopic radiographic angiography, and radionuclide imaging. Compared with echocardiography and radionuclide imaging, CMR and CCT offer superior anatomic scope and spatial resolution. CMR is the noninvasive, nonionizing reference standard for evaluation of volumetric left ventricular (LV) and right ventricular (RV) cavity size, systolic function, and LV mass, providing highly reproducible measures for noninvasive follow-up of disease processes. CCT measures of LV cavity size and systolic function compare favorably with CMR.⁴ In contrast to echocardiography and nuclear imaging, CMR permits unrestricted image acquisition orientation, which can be readily adjusted to particular patient and study requirements. Although CCT acquisitions are always in the axial plane, high isotropic spatial resolution facilitates post-processing reconstruction in any desired orientation. There is also relatively advanced post-processing software for CCT. In contrast, echocardiography offers the advantages of portability, lower cost, lack of ionizing radiation (like CMR), widespread availability, greater ease of patient monitoring, and greater sensitivity for structures with chaotic motion, such as vegetations. Further comparisons among CMR, CCT, and other techniques will be made in later sections dealing with specific types of examinations.

IMAGING PRECAUTIONS

Precautions generally applicable to body magnetic resonance imaging (MRI) are applicable to CMR. Before imaging, all patients must undergo detailed screening for any potential contraindications to CMR. In addition to general concerns of metallic implants and severe claustrophobia, patients should be screened for the presence of any incompatible material. Excluded devices include some that are relatively common among those with cardiovascular disease, such as pacemakers, unconnected or retained permanent pacing leads, and implantable cardioverter-defibrillators. Protocols for scanning of non-pacemaker-dependent patients with modern (implanted after 2000) pacemakers or implantable cardioverter-defibrillators have been reported.⁵ In addition, special MR conditional pacemakers are now available and should be considered for patients likely to need future MR studies.^{6,7} Bioprosthetic and mechanical heart valves, sternotomy wires, thoracic vascular clips, and intracoronary stents are generally considered CMR-safe at field strengths up to 3 T (see www.mrisafety.com), although they may produce local artifacts that reduce image quality.⁸ Because of bulk cardiac motion during systole and diastole, most CMR protocols require ECG triggering with images composed from data collected during multiple successive cardiac cycles. Despite this, good functional image quality can usually be obtained among patients with atrial fibrillation, although image quality may be impaired among subjects with frequent

premature beats. Among patients with irregular rhythms, non-ECG gated real-time imaging CMR (which permits real-time image acquisition analogous to two-dimensional echocardiography but at lower spatial and temporal resolutions than that attained with a gated CMR technique) can provide useful information.⁹ Arrhythmias and tachycardia will also lead to suboptimal CCT data image quality.¹⁰ Compared with CMR, where the sequences are adapted for the patient's heart rate, CCT is restricted by gantry rotational speed and often requires β -blockers to slow the heart rate to 60 beats/min or less for coronary studies.² All subjects require appropriate monitoring during their imaging studies. Basic monitoring modalities include ECG monitoring for rate and rhythm (pulsatile blood in the magnetic field distorts the ST segment appearance, rendering the ST wave uninterpretable during CMR), intercom voice contact, and visualization (by direct view, camera, or both). For patients requiring a greater intensity of monitoring, automated cuff blood pressure monitoring and pulse oximetry can be added, especially for hemodynamically unstable patients and for stress CMR.

As noted earlier, CMR often does not require an exogenous contrast agent. When needed, however, gadolinium-containing CMR contrast agents have a much more favorable safety profile in regards to both nephrotoxicity and anaphylaxis compared with the iodinated agents used in CCT.¹¹ Administration of gadolinium contrast to patients with severe renal dysfunction can result in nephrogenic systemic fibrosis, a rare but severe scleroderma-like disorder that can result in death.^{12,13} Patients at high risk of renal dysfunction are screened with a Choyke questionnaire to identify those at increased risk for renal dysfunction.¹⁴ For these patients, a determination of the estimated glomerular filtration rate (eGFR) is required. Patients with mild renal impairment (eGFR 30–60 mL/kg per 1.73m²) can be safely imaged with a reduced dose of contrast agent. Noncontrast CMR or alternative imaging modalities should be considered for patients with severe renal dysfunction (eGFR < 20 mL/kg per 1.73m²), especially those on dialysis.

Because of the general requirement for iodinated contrast, CCT must be performed with caution in patients with renal insufficiency, as in patients with diabetes and use of nonsteroidal antiinflammatory drugs—factors associated with an increased risk of contrast-induced nephropathy.¹⁵ Alternative noninvasive imaging methods are preferable in the setting of moderate or greater renal insufficiency, unless dialysis has already been instituted. Proper hydration with saline solution is recommended, and bicarbonate solution and *N*-acetylcysteine may reduce the incidence of acute renal failure because of iodinated contrast, despite significant heterogeneity among studies.^{16–18}

Radiation exposure is a significant consideration in the use of CCT, especially for younger patients who are more likely to have numerous CT scans during their lifetime and have increased susceptibility to the harmful effects of ionizing radiation. With the technology moving from four-slice to 320-detector scanners, a significant reduction in radiation has been achieved.¹⁹ Dose reduction technologies including lower tube voltage, prospective

gating, and dose modulation permit further reduction in the effective dose from 12 to 20 mSv to 4 to 7 mSv²⁰ without compromising diagnostic accuracy.²¹

CLINICAL APPLICATIONS

Diseases of the Thoracic Aorta

Both CMR and CCT are widely used clinically for the assessment of the thoracic aorta for aneurysms and dissection. With CMR, the structure of the aorta is delineated by a combination of the following protocol components in the transverse, coronal, sagittal, and oblique planes: (1) ECG-gated spin-echo imaging, which reveals the aortic wall with rapidly flowing blood appearing black and thrombuslike, and slowly moving blood appearing gray; (2) ECG-gated SSFP imaging with bright-blood images in single-shot and cine acquisitions; and (3) three-dimensional CE-MRA using a gradient echo acquisition. Temporally resolved CE-MRA is particularly useful to minimize motion artifacts that would otherwise result in nondiagnostic or false-positive results. With CCT, imaging of the aorta involves iodinated contrast with a larger image acquisition volume to include the entire thoracic aorta and can be performed with or without ECG gating. ECG gating is preferred for the CCT evaluation of dissection to avoid motion artifacts that can mimic a dissection flap.

Aortic Aneurysm

Cardiovascular magnetic resonance and CCT are both superior methods for identification of true and false thoracic aortic aneurysms. In true aneurysms, the aneurysmal aortic wall is composed of intima, media, and adventitia. False aneurysms represent a contained rupture of the intima and media, with only the adventitia and periadventitial connective tissue limiting the hemorrhage (Fig. 53-1). False aneurysms generally have a narrow

“neck” or communication with the main aortic lumen. True aneurysms are more commonly fusiform (bulge aligned along the long axis of the aorta; Fig. 53-2) than saccular (sacklike bulge extending from a side of the aortic wall). CE-MRA reveals the presence and extent of these lesions as well as any associated thrombus. CCT is recommended as the imaging modality of choice for most patients in the assessment of acute disease, whereas three-dimensional CE-MRA is preferred for most patients with chronic disease requiring long-term monitoring. As with aortic dissection, advantages of CMR and CCT assessment compared with radiographic angiography include the capability to evaluate for associated complications such as hemopericardium and LV dysfunction. CMR can also assess for the presence of associated aortic regurgitation. After composite graft replacement of the ascending aorta, CMR and CCT are useful for detection of postoperative complications, such as leakage or hematoma

FIGURE 53-1 ■ Ruptured aorta. Non-electrocardiograph-gated contrast-enhanced cardiovascular computed tomography axial image of the aorta at the level of the aortic arch. There is a contained rupture of the ascending aorta, with blood and thrombus filling the mediastinum (white arrow) and a hemorrhagic left pleural effusion (black arrowheads).

FIGURE 53-2 ■ Aortic aneurysm. Non-contrast-enhanced cardiovascular magnetic resonance in the transverse (A) and oblique sagittal (B) imaging planes of a patient with a descending thoracic aortic aneurysm (arrow) partially filled with thrombus (arrowhead). Each image was acquired in less than 1 second with the steady-state free-precession sequence without the administration of an exogenous contrast agent. (Courtesy Tim Leiner, MD, PhD.)

formation,²² with CMR offering the option for noncontrast methods.

Aortic Dissection

Cardiovascular magnetic resonance and CTT, along with transesophageal echocardiography (TEE), are the primary methods used to diagnose patients with acute aortic dissection. Because each of these imaging modalities has high diagnostic accuracy for dissection, the selection among these methods is generally governed by patient condition, institutional access, and local expertise. In a meta-analysis,²³ the three modalities showed high specificities and sensitivities in a setting of high pretest probability (>40%), but the pooled positive likelihood ratio was highest for MRI. CMR and CCT provide information regarding involvement of major branch vessels and all segments of the aorta, unlike TEE, which is limited to the thoracic aorta and by the adequacy of acoustic windows (particularly for the segment of ascending aorta anterior to the trachea). All three methods provide useful information regarding pericardial involvement. CMR and TEE can also assess aortic valve integrity. The main disadvantages of CMR in the acute setting are potential obstacles to continuous monitoring and care of an unstable patient during transport and performance of the study and the requirement that the patient remain motionless during the examination. CCT is much faster and is frequently available in the emergency department. Thus, CCT is the most common initial imaging modality chosen to diagnose *acute* aortic dissection,²⁴ whereas CMR is considered the imaging procedure of choice for *serial monitoring* of the medically or surgically treated patient with dissection according to the Recommendations of the Task Force on Aortic Dissection of the European Society of Cardiology (which have been endorsed by the American College of Cardiology) because of the lack of radiation exposure.²⁵ Follow-up is recommended after hospital discharge at 1, 3, 6, and 12 months, and yearly thereafter, ideally using the same modality.²⁵ Accurate interpretation of postoperative images requires knowledge of the surgical procedure and the expected range of routine postoperative sequelae including

thickening around the graft and presence of thrombus outside the graft and within the native aortic wrap.^{24,25}

CCT aortic assessment is typically completed in less than 1 minute, and often in less than 30 seconds, whereas CMR aortic assessment may require up to 20 minutes to complete. Both can display the location and extent of dissection identified as an intimal flap separating true and false aortic lumina, along with sites of intraluminal communication, and can readily assess involvement of the aortic root, arch vessels, and renal arteries (Fig. 53-3). CMR spin-echo images may identify relatively bright regions within the true or false lumen attributable to stagnant blood flow or thrombus. Cine SSFP images demonstrate flap motion and blood flow in the true and false lumen. Three-dimensional CE-MRA is highly sensitive for dissection²³ and can be implemented with sub-second temporal resolution to obviate the need for a breath-hold (Fig. 53-4).²⁶ Alternatively, three-dimensional free-breathing SSFP imaging without exogenous contrast can be accomplished with accuracy similar to CE-MRA (see Fig. 53-2).²⁷ LV function and involvement of the proximal coronary arteries can be assessed by CCT with a gated acquisition or using CMR with coronary imaging. Importantly, CMR can also assess the presence of coexistent aortic valve involvement (using cine imaging of the LV outflow tract) and the severity of aortic regurgitation (using a phase velocity-encoding acquisition at the base of the aortic root).

Aortic Intramural Hematoma

Intramural hematoma can be identified by the presence of a localized thickening, frequently crescentic or circular, within the wall of the aorta, interposed between the intima and the media, with characteristics of an acute or subacute collection of blood.²⁸ Although both CMR and CCT can identify intramural hematoma, CMR has been found to be superior to CCT in distinguishing acute intramural hematoma from atherosclerotic plaque and chronic intraluminal thrombus.²⁹ Acute hemorrhage appears as isointense or more intense compared with the aortic wall on T1-weighted images and displays high signal intensity on T2-weighted images. In contrast,

FIGURE 53-3 ■ Aortic dissection. Axial images of aortic dissection from the same patient. **A**, T1-weighted spin-echo cardiovascular magnetic resonance shows a dissection flap (arrow) in the ascending aorta. Note the increased signal in the false lumen (asterisk) caused by slow blood flow. **B**, Electrocardiograph-gated contrast-enhanced cardiovascular computed tomography axial image at the same location as the cardiovascular magnetic resonance image. The dissection flap (arrow) is again identified in the ascending aorta.

FIGURE 53-4 ■ Aortic dissection. The three-dimensional contrast-enhanced cardiovascular magnetic resonance oblique image of the thoracic aorta demonstrates a DeBakey classification type 1 dissection (arrows) involving the ascending and descending thoracic aorta.

subacute hemorrhage displays high signal intensity on T1 images and less signal intensity on T2 images. The layer of displaced calcified intima overlying the hematoma generally produces a relatively smooth surface concave to the lumen (crescentic shape), which may help to distinguish this entity from protuberant, frequently irregularly shaped, atherosclerotic plaque.

Sinus of Valsalva Aneurysm

A sinus of Valsalva aneurysm is often first suggested on transthoracic echocardiography and can be readily visualized by CCT, CMR, and TEE as an enlargement or outpouching (frequently creating a “windsock” appearance) of a sinus of the aortic root. In addition, CMR and echocardiography offer the advantage of providing information regarding blood flow (e.g., rupture of the aneurysmal sinus into an adjacent chamber) in addition to anatomy (Fig. 53-5). Shunt flow through the rupture is generally present in both diastole and systole. The magnitude of the shunt can be calculated using CMR flow velocity-encoding data.

Atherosclerotic Plaque and Aortic Penetrating Ulcer

Cardiovascular magnetic resonance, CCT, and TEE can provide qualitative and quantitative information about the presence, thickness, and distribution of atherosclerotic plaque in the aorta.³⁰⁻³³ Complex plaque is generally defined as protuberant plaque greater than or equal to 4 mm in thickness (or plaque with mobile elements)

FIGURE 53-5 ■ Sinus of Valsalva aneurysm. Steady-state free-precession cine cardiovascular magnetic resonance image of a ruptured sinus of Valsalva aneurysm (arrowhead) with signal void (arrow) in the right ventricle from associated turbulent flow.

because plaque with these characteristics is associated with increased embolic risk.³⁴ Plaque thickness can readily be ascertained by CMR, CCT, and TEE, although overlying mobile elements are best assessed by TEE because of their chaotic motion and relatively small size.³⁵ Ascending aortic plaque is a predictor of adverse cerebral outcomes after coronary artery bypass grafting. Preoperative (CMR or CCT) or intraoperative (TEE) identification of ascending aortic plaque may prompt alteration in surgical strategy or technique.^{34,36}

Aortic ulceration occurs in regions of atherosclerotic plaque. Penetrating ulcers are described as those breaching the internal elastic lamina, with associated hematoma formation in the media.³⁷ CMR and CCT images visualize the position and shape of such ulcers and accompanying adjacent intramural hematoma.^{29,32,35} Penetrating ulcers are also frequently associated with aortic aneurysm formation.^{38,39} The presence of associated chest or back pain is a significant risk factor for progression to pseudoaneurysm or free rupture.³⁸

Takayasu Arteritis

Takayasu arteritis is a chronic idiopathic vasculitis that primarily affects the aorta and its branches. It is most prevalent among Asian women younger than 40 years of age.^{40,41} The aortic arch (or distal aorta) and its branches, as well as the pulmonary arteries, have characteristically tapered narrowings or occlusions, with areas of dilation. The availability of noninvasive imaging is important among these patients, who require serial long-term follow-up to guide their medical and surgical therapy. These lesions have been traditionally detected by conventional radiographic angiography, but CMR and CCT can accurately display these lesions and also provide information regarding a vessel wall abnormality.^{42,43} CMR is generally preferred to CCT because of the need for repeated imaging in these younger women and the desire

to minimize ionizing radiation exposure. Evidence of vessel wall edema is common but does not correlate well with subsequent lesion development.⁴⁴ Therefore, the current role of imaging in this disease is to identify and monitor the characteristic angiographic lesions.

Congenital Aortic Anomalies

Both CMR and CCT can readily identify and characterize aortic coarctation, patent ductus arteriosus, and other congenital abnormalities involving the great vessels. The choice is based on local expertise/availability and issues related to patient age and renal function. When available, CMR imaging is usually preferred to CCT for evaluation of congenital aortic anomalies because of concerns about radiation exposure in this generally younger population and the likely need for serial lifelong studies.

Aortic coarctation is characterized by a ridge of medial thickening and intimal hyperplasia along the posterolateral aortic wall. Coarctation most commonly presents just distal to the take-off of the left subclavian artery, occurring more rarely just proximal to the left subclavian artery. Anatomic assessment with CMR or CCT reveals the location of the coarctation and associated collaterals, usually assessed in an oblique sagittal view aligned with the descending and ascending thoracic aorta (Fig. 53-6).⁴⁵ Typical CMR protocols use spin-echo, gradient-echo, and CE-MRA techniques.^{46,47} Additional cardiac lesions that frequently accompany coarctation can also be identified, including bicuspid aortic valve (imaged in cross section) and ventricular septal defect (imaged in a horizontal long-axis or four-chamber view). Imaging is also useful for follow-up after surgical repair or balloon angioplasty,^{46,48} and routine CMR follow-up has been recommended.⁴⁹ Potential complications that may be visualized include renarrowing and aneurysm or pseudoaneurysm at the repair site.

Although patent ductus arteriosus can usually be identified by transthoracic echocardiography, CMR or CCT may be useful when echocardiographic images are non-diagnostic because of poor acoustic windows.⁵⁰ For both patent ductus arteriosus and atrial or ventricular septal defect, CMR also provides a quantitative assessment of the pulmonic-to-systemic flow ratio (Qp:Qs) by applying the flow velocity-encoding technique.⁵¹

FIGURE 53-6 ■ Aortic coarctation. Non-electrocardiograph-gated contrast-enhanced axial cardiovascular computed tomographic image at the level of the aortic arch shows severe narrowing of the aorta (arrow).

Thoracic Trauma

Aortic trauma is usually related to rapid body deceleration, more frequently at the aortic isthmus, immediately distal to the origin of the left subclavian artery.⁵² Aortic lesions are graded according to lesion extension: intimal tear (Grade I), intramural hematoma (Grade II), pseudoaneurysm (Grade III), and total rupture (Grade IV). Grades II and III lesions may be localized or circumferential, and delayed selective repairs have a relatively good prognosis.⁵³ Chest radiography and emergency department CCT are generally the initial imaging modalities used for the assessment of acute thoracic trauma. In addition to providing information about the thoracic aorta, CCT also provides a comprehensive assessment of the thoracic anatomy, including the chest wall, mediastinum, diaphragm, and vertebrae. CMR may be useful for assessment of diaphragmatic, mediastinal, and aortic injury if CCT results are equivocal, and for characterizing post-traumatic masses such as intramural hematomas and aneurysms.^{54,55}

Preoperative Evaluation for Redo Cardiac Surgery

Revisited cardiac surgery is more frequently related to previous coronary artery bypass grafts and is associated with an almost threefold increase in in-hospital mortality compared with first-time procedures.⁵⁶ Accurate CCT or CMR assessment of mediastinal anatomy, including retrosternal adhesences, distances of the sternum to the aorta, the RV free wall, the left internal mammary artery, and other grafts, may lead to modifications in surgical strategies and reduce surgical complications and mortality.⁵⁷

Cardiac Imaging

Ventricular Structure and Function

CMR is the reference noninvasive, nonionizing radiation modality for the quantitative assessment of the LV and RV chamber sizes, systolic function, and LV mass, with greater reproducibility than that available using other nonvolumetric techniques.⁵⁸ Gender-specific normal reference values for CMR LV mass, volume, and ejection fraction have been defined.^{59,60} A set of breath-hold two-chamber, four-chamber, and short-axis cine SSFP images spanning the ventricles can be acquired within 10 minutes without an exogenous contrast agent. SSFP techniques provide superior endocardial border definition, thereby enabling use of semiautomated techniques for image analysis.⁶¹ Regional systolic function can be assessed by examining segmental wall motion and thickening in the different planes. A 17-segment LV model common to echocardiography and nuclear cardiology is recommended.⁶² Evaluation of LV cavity size and systolic function with CCT requires acquisition of images throughout the cardiac cycle with iodinated contrast and with or without dose modulation. Images are usually reconstructed at 10% intervals over the entire cardiac cycle. The entire three-dimensional volume is reconstructed and displayed as a cine, with most centers evaluating 2D

FIGURE 53-7 ■ Late gadolinium enhancement cardiovascular magnetic resonance two-chamber (A) and midventricular short-axis (B) views in a patient with an inferior myocardial infarction. The region of late contrast enhancement (arrows) corresponds to scar.

slices in the two-chamber, four-chamber, and short-axis orientations. Even though assessment of the RV may be impaired because the passage of contrast material through the heart is timed to maximize opacification of the LV, it is possible to obtain accurate and reproducible RV measurements compared with CMR.^{4,63,64} Regional and global LV and RV systolic function is most commonly assessed clinically by transthoracic echocardiography because of its widespread availability, portability, and relative ease of use. Echocardiographic assessment is frequently limited by variability of views and suboptimal image quality. CMR and CCT offer advantages compared with echocardiography in providing superior image quality and more accurate and reproducible volumetric quantification of both systolic function and cavity size.

Identification of Myocardial Scar and Ischemia

The detection of scar using an LGE CMR has proved to be highly sensitive for determining the presence and spatial extent of acute and chronic myocardial infarction identified as regions of subendocardial-based hyperenhancement (Fig. 53-7),⁶⁵ which closely agrees with positron emission tomography data.⁶⁶ Among patients with resting regional LV systolic dysfunction, visualization of the presence and distribution of scar and viable myocardium within dysfunctional regions identifies patients who would benefit from revascularization.⁶⁷ Analogous to transthoracic echocardiographic methods, low-dose dobutamine CMR also provides viability assessment and is especially valuable for those in which there is an intermediate LGE thickness.⁶⁸

Pharmacologic CMR stress testing is useful for assessment of ischemia by induction of either wall motion abnormalities (dobutamine) or perfusion defects (vasodilator with adenosine, dipyridamole, or regadenoson). Although CMR is not as widely used, its accuracy for coronary artery disease surpasses that of myocardial perfusion single photon emission computed tomography imaging⁶⁹ and allows for the identification of patients at low risk for cardiovascular events.⁷⁰ CCT applications for the detection of scar and evaluation of myocardial perfusion are in development^{71,72} but are currently limited because of relatively high radiation exposure and dose of iodinated contrast.

FIGURE 53-8 ■ Hypertrophic cardiomyopathy. Steady-state free-precession cine cardiovascular magnetic resonance four-chamber image in a patient with hypertrophic cardiomyopathy with asymmetrical septal hypertrophy.

Cardiomyopathies

Cardiovascular magnetic resonance and CCT are both useful in characterizing LV and RV structure and function among patients with nonischemic cardiomyopathy. The high reproducibility of these measures of biventricular cavity size and function makes them a valuable tool for quantitative serial assessment among patients with dilated cardiomyopathy, with the favorable advantage of CMR for its nonionizing, noncontrast characteristics.

Among patients with hypertrophic cardiomyopathy, CMR and CCT can accurately delineate the distribution of hypertrophy among ventricular segments free of limitations (such as foreshortening of the apex and off-axis views) encountered by echocardiography. Thus, these imaging modalities are particularly helpful in identifying asymmetric or apical hypertrophy (Fig. 53-8) as well as apical aneurysms.⁷³ Among patients with hypertrophic cardiomyopathy, LGE CMR identifies regions of

FIGURE 53-9 ■ Arrhythmogenic right ventricular cardiomyopathy. Spin-echo cardiovascular magnetic resonance without (A) and with (B) a fat-suppression prepulse. There is bright signal in the free wall of the right ventricle that suppresses with fat suppression (arrows).

myocardial fibrosis that may be associated with an adverse prognosis.⁷⁴ An LGE pattern at the junction of the interventricular septum with the RV free wall is characteristic in hypertrophic cardiomyopathy.⁷⁵

CMR provides unique information for certain specific types of cardiomyopathy. LGE images may detect focal myocardial abnormalities associated with sarcoidosis.⁷⁶ Hemochromatosis with myocardial iron deposition and LV dysfunction is associated with a depressed T_2^* .^{77,78} CMR serves as a cornerstone for diagnosis of arrhythmogenic RV cardiomyopathy to determine RV cavity size, to evaluate global and regional RV free-wall function, and to detect any fibrofatty infiltration of myocardium,⁷⁹⁻⁸¹ although the specificity and sensitivity of these findings have not been fully defined (Fig. 53-9).⁸²

CMR and CCT can also be useful for discriminating between cardiomyopathy resulting from ischemic and nonischemic causes. CMR can identify the presence of subendocardial LGE suggestive of prior infarction or coronary artery disease,^{83,84} which helps in diagnosing nonischemic cardiomyopathy in new-onset heart failure,⁸⁵ with a high predictive value for excluding the presence of left main or three-vessel coronary disease.⁸⁶ CCT also has excellent accuracy for excluding left main or three-vessel disease.⁸⁷ In nonischemic cardiomyopathy, the detection of midwall and epicardial LGE has been shown to predict events independently of LV ejection fraction.^{88,89}

Congenital Heart Disease

Cardiovascular magnetic resonance plays an important role in the diagnosis and management of simple and complex congenital heart disease.⁹⁰ The lack of ionizing radiation exposure is of particular importance for patients who often undergo numerous monitoring tests during their lifetime. Its capabilities are complementary to those of echocardiography and cardiac catheterization and are particularly useful among children and adults with sub-optimal acoustic windows and those with complex lesions. CMR can effectively identify the location, orientation, and relationships among the vena cavae, cardiac chambers, valves, great vessels, and pulmonary veins. Anatomic structure can be displayed in tomographic views

FIGURE 53-10 ■ Scimitar syndrome. Scimitar syndrome is a rare form of partial anomalous pulmonary venous connection in which the entire right lung drains into the inferior vena cava. This contrast-enhanced cardiovascular magnetic resonance coronal maximal intensity projection in the anterior-posterior orientation shows the typical findings of scimitar syndrome. The single right pulmonary vein (RPV) enters the inferior vena cava (IVC). The right atrium (RA) and descending aorta (AoD) are also shown. (Courtesy Andrew Powell, MD.)

and in three-dimensional reconstructions, which delineate complex spatial relationships (Fig. 53-10). In addition, CMR flow velocity-encoding scans can be used for measurement of flow and thus quantify the magnitude of intracardiac shunts associated with atrial and ventricular septal defects (Fig. 53-11) and conduits.⁹¹ Aortic forward and regurgitant volume can be quantified by flow velocity-encoding imaging in an axial (or oblique) plane transverse to the long axis of the ascending aorta.

FIGURE 53-11 ■ Sinus venosus atrial septal defect. **A**, Four-chamber steady-state free-precession cine cardiovascular magnetic resonance image of a sinus venosus atrial septal defect (arrow). Phase-velocity cardiovascular magnetic resonance at the level of the pulmonary artery (**B**, arrow) and aortic root (**C**, arrow) and corresponding flux contours indicate a pulmonary-to-systemic shunt ratio ($\dot{Q}_p/\dot{Q}_s$) of 3.0.

Similarly, flow velocity–encoding in a cross-sectional slice of the proximal main pulmonary artery (oblique, generally near the coronal orientation) enables quantification of pulmonary artery forward and regurgitant volume. The ratio of pulmonary and aortic (forward) flows ($\dot{Q}_p/\dot{Q}_s$) can be calculated to identify and quantify a significant ($\dot{Q}_p/\dot{Q}_s > 1.5$) intracardiac shunt.⁹¹ CMR is particularly helpful for volumetric quantitation of RV size and function, which is important for clinical assessment of many types of congenital heart disease.⁹²

CCT has a similar utility in the assessment of the anatomy of the heart and great vessels in congenital heart disease but is less valuable for quantifying blood flow. However, CCT can be helpful in the evaluation or follow-up of congenital heart disease in the adult population and in patients with a contraindication to CMR

imaging.⁹³ Application of CCT in this setting requires careful attention to the reduction of radiation exposure and the timing of contrast administration to delineate the anatomy of interest.

Cardiac and Paracardiac Masses

Cardiovascular magnetic resonance and CCT can readily delineate cardiac and paracardiac masses such as tumors, myxomas, and thrombi.⁹⁴ A particular benefit of both methods is for masses that extend outside of the heart. Intracardiac masses are usually initially detected by transthoracic echocardiography and are frequently effectively characterized by echocardiography alone. When echocardiographic images are suboptimal or do not adequately define the extent of the mass, further imaging with CMR

FIGURE 53-12 ■ Myocardial fibroma. **A**, Steady-state free-precession cine cardiovascular magnetic resonance image of the left ventricular outflow tract shows a well-circumscribed intramyocardial mass with low signal (*arrow*). The mass had low signal on T1 weighting (**B**), T2 weighting (**C**), and T1 weighting after administration of contrast material (**D**) on spin-echo imaging in the two-chamber view (*arrows*), indicating calcification of the mass. These findings are consistent with a fibroma.

or CCT will define the characteristics and spatial extent of the mass within and beyond the cardiac borders. The three-dimensional characterization of the mass is often helpful for surgical planning. Characterization of masses based on T1-weighted, T2-weighted, fat-suppression techniques, cine CMR, and postcontrast imaging is useful (Fig. 53-12).⁹⁵

Intracardiac thrombus is generally suspected from the appearance of a mass in a region of blood stasis (such as an aneurysmal or akinetic LV apex) on either CMR or CCT. The appearance of thrombus on CMR varies with the time. Early thrombus is seen as a region of high-signal intensity on T1- and T2-weighted images. After one to two weeks, higher signal intensity may be noted on T1-weighted images and decreased signal intensity on T2-weighted images. Chronic thrombi have low signal intensity, with even greater signal loss in regions of calcification. LGE CMR shows a greater sensitivity than echocardiography to detect a thrombus, particularly mural thrombi in patients with ischemic heart disease (Fig. 53-13).^{96,97}

Pericardial Disease

Echocardiography is frequently the initial modality used in suspected pericardial disease. However, CMR and CCT have superior imaging capabilities, including a wide field of view, and superior identification and characterization of pericardial masses and cysts, effusions (especially

FIGURE 53-13 ■ Late gadolinium-enhancement cardiovascular magnetic resonance in the four-chamber view in a patient with a left ventricular thrombus (*arrow*) adjacent to the bright area of transmural late gadolinium enhancement (scar).

loculated effusions), and pericardial thickening.⁹⁸ With CMR, a pericardial effusion has low signal intensity (relatively dark) on T₁-weighted images and high signal intensity (bright) on T₂-weighted and gradient-echo scans. LGE CMR demonstrates marked enhancement of the pericardium in patients with acute pericarditis⁹⁹ and may help to identify patients who would benefit from medical therapy (Fig. 53-14).¹⁰⁰ With CCT, pericardial effusion has an intermediate attenuation that stands apart from the low-attenuation visceral and parietal pericardial fat (Fig. 53-15). Iodinated contrast is not typically required to assess the pericardium with CCT. Both CCT and CMR are particularly useful for identifying loculated effusions and any accompanying pericardial masses or pericardial thickening.

Although the diagnosis of constrictive pericarditis requires clinical assessment for constrictive physiology, CMR and CCT can effectively identify focal regions of pericardial thickening characteristic of this disorder.^{101,102} CCT is preferred for identification of pericardial calcifications (which lack signal by CMR) (Fig. 53-16).¹⁰¹ On spin-echo CMR images, normal pericardial thickness is less than or equal to 3 mm. Among patients with pericardial constriction, the CMR pericardial thickness is generally greater than 6 mm,^{102,103} with 4 to 6 mm being intermediate. Pericardial thickening associated with constriction is frequently focal, so identifying the location of thickening may be important to the surgical approach. Spin-echo images instead of gradient-echo images should be used to assess pericardial thickness because the latter may overestimate pericardial thickness and fail to distinguish between patients with and without constriction.¹⁰⁴

FIGURE 53-14 ■ Pericarditis. Late gadolinium-enhancement cardiovascular magnetic resonance image in the short-axis view at the level of the mid-ventricle shows circumferential enhancement of the pericardium.

ECG-gated acquisitions are useful in demonstrating abnormal early diastolic septal motion characteristic of constriction. CMR tagging methods are also useful in identifying regions of parietal to visceral pericardial adherence (Fig. 53-17).¹⁰⁵ In these areas, lack of free sliding between the pericardial layers during the cardiac cycle is visualized as persistent continuity in tag lines crossing the pericardial interface (lines deform but do not break).

Valvular Heart Disease

Although echocardiography is used most commonly in clinical practice for the assessment of valvular morphology and stenosis, CMR offers specific advantages for the quantitative assessment of valvular regurgitation. Qualitative assessment of valvular regurgitation can be made from the flow disturbance (signal void) on cine images,

FIGURE 53-15 ■ Pericardial effusion. Nongated cardiovascular computed tomographic image with a moderate pericardial effusion predominantly displayed in the dependent portion of the pericardium (*asterisk*) but also visible as a thin line at the anterior aspect of the heart (*arrowhead*).

FIGURE 53-16 ■ Non-electrocardiograph-gated contrast-enhanced axial cardiovascular computed tomographic image of a patient with pericardial constriction and pericardial calcification (*arrowheads*).

FIGURE 53-17 ■ Effusive-constrictive pericarditis. Axial dual-inversion T1-weighted (**A**) and cine steady-state free-precession (**B**) cardiovascular magnetic resonance images of a patient with effusive-constrictive pericarditis. Pericardial fluid appears relatively bright; pericardium and organized material appear dark. The end-systolic tagged four-chamber image (**C**) demonstrates tethering of pericardial elements to the right ventricular (*arrow*) and left ventricular (*arrowhead*) walls.

FIGURE 53-18 ■ Aortic regurgitation. **A**, Steady-state free-precession cine cardiovascular magnetic resonance image of the left ventricular outflow tract shows an eccentric jet of turbulent flow indicating aortic regurgitation (*arrowhead*). **B**, Flow contour from a phase-contrast acquisition in the aortic root just above the aortic valve indicates significant negative diastolic flow, which can be quantified.

although the magnitude of the signal void is reduced with SSFP images, which use short echo times. Importantly, flow velocity-encoding is a powerful technique for quantifying the regurgitant volume (Fig. 53-18). Flow velocity-encoding scans of the aortic root in axial or oblique (near axial) cross-sectional views enable quantitation of aortic forward and regurgitant volumes. The difference between LV stroke volume (derived from summation of discs method applied to a contiguous stack of

short-axis images spanning the LV) and forward aortic flow volume is a quantitative measure of mitral regurgitation. The regurgitant fraction can be calculated as the ratio of the regurgitant volume to total stroke volume. Using these techniques, CMR and echocardiography have very good agreement in the assessment of mitral and aortic regurgitation using equivalent severity thresholds.¹⁰⁶ Analogous methodology can be performed for pulmonary and tricuspid regurgitation.

FIGURE 53-19 ■ Aortic valve disease. Steady-state free-precession cine cardiovascular magnetic resonance (CMR) (A) and cardiovascular computed tomography (CCT) (B) images of a trileaflet, calcified, and stenotic aortic valve in short axis. State free-precession CMR (C) and CCT (D) of a stenotic bicuspid aortic valve.

Cross-sectional and longitudinal views of the valves can be used to characterize valve deformities and stenosis (Fig. 53-19). CCT and CMR measures of aortic stenosis agree very closely with both transthoracic and TEE measurements.¹⁰⁷ Flow velocity-encoding techniques¹⁰⁸ may be useful in estimating valve gradients, and four-dimensional CMR flow is a promising technique to evaluate flow patterns.¹⁰⁹

CCT and CMR, as much as TEE, are also recommended for the correct assessment of the aortic root size and anatomy in the planning of transcatheter aortic valve implantation.¹¹⁰ Even though CCT is most frequently used, CMR provides accurate measurements and has a role in patients with restrictions to using iodinated contrast.²¹

Coronary Artery Imaging

Noninvasive coronary artery imaging is technically demanding, with maximal demands on spatial, temporal, and contrast resolution. Current coronary MRA imaging protocols incorporate methodology to suppress the effects of cardiac motion and respiratory motion.¹ Cardiac motion is addressed via robust ECG signal detection to trigger gating and customized adjustment of the acquisition window for patient-specific diastasis periods. Respiratory motion artifacts are suppressed by CMR navigators or prolonged breath-holds.¹¹¹ To enhance contrast between blood in the coronary arteries and the surrounding myocardium and epicardial fat, a T2-weighted preparation prepulse and a frequency-selective fat-saturation prepulse are applied. A three-dimensional acquisition is used to

FIGURE 53-20 ■ Anomalous coronary artery. The three-dimensional coronary cardiovascular magnetic resonance image reformatted in the axial plane indicates an anomalous origin of the left main coronary artery (black arrow) from the right sinus of Valsalva. The left coronary artery courses between the aorta and the main pulmonary artery (malignant form) before bifurcating into the left anterior descending and left circumflex arteries (arrowheads). The right coronary artery (white arrow) originates normally from the right sinus of Valsalva.

enhance the SNR, although the SNR is somewhat diminished by the prepulses required to optimize the contrast-to-noise ratio. Three-dimensional images can be prescribed as either two separate volume targeted acquisitions for the left and right coronaries or as a single whole-cardiac volume,¹¹² each with its own advantages but similar quality.¹¹³ High-field (3 T) coronary artery CMR and gadolinium-based contrast agents also appear promising.^{114,115}

The most appropriate clinical use of coronary artery CMR is for the identification and characterization of anomalous coronary arteries. Studies comparing coronary artery CMR with conventional radiographic coronary angiography reveal equivalent to superior accuracy in the identification of anomalous coronary arteries.¹¹⁶⁻¹¹⁸ Because coronary artery CMR demonstrates the origin and course of each coronary artery in three-dimensional relation to the great vessels, it can resolve spatial ambiguity sometimes encountered when interpreting conventional projection radiographic coronary angiographic

images.¹¹⁶⁻¹¹⁸ Coronary artery CMR is particularly helpful in identifying whether the anomalous artery courses between the aorta and the pulmonary artery^{119,120} (Fig. 53-20), a malignant configuration associated with sudden death and myocardial infarction among young adults.¹²¹ In addition, among patients undergoing cardiac surgery for repair or palliation of other congenital defects, it may be important to identify and define any coincident anomalous coronary arteries to avoid inadvertent iatrogenic injury.¹²² Although CCT is also very good at detecting the presence and course of anomalous coronary arteries,¹²³ CMR is typically preferred in this generally younger age population because of its lack of radiation exposure.¹²⁴

CMR effectively identifies significant stenoses in the proximal to mid-native coronary arteries, with an 87% accuracy in diagnosing left main coronary artery disease or three-vessel disease, and a 72% accuracy in diagnosing coronary artery disease (defined as a $\geq 50\%$ diameter stenosis on radiographic angiography; Fig. 53-21).⁸⁶

FIGURE 53-21 ■ Coronary artery disease. **A**, Coronary cardiovascular magnetic resonance image with a three-dimensional gradient-echo sequence (left) and a corresponding radiographic coronary angiogram (right) indicate a severe lesion at the bifurcation of the left main coronary artery (solid arrows) and a more distal focal stenosis of the proximal left circumflex coronary artery (broken arrows). **B**, A coronary cardiovascular magnetic resonance image (left) and a corresponding radiographic angiogram (right) indicate two stenoses of the proximal (solid arrows) and middle (broken arrows) right coronary artery. AA, Ascending aorta; LA, left atrium; LV, left ventricle; PA, pulmonary artery; RV, right ventricle; RVOT, right ventricular outflow tract. (From Kim WY, Danias PG, Stuber M, et al: Three-dimensional coronary magnetic resonance angiography for the detection of coronary stenoses. *N Engl J Med* 345:1863-1869, 2001; with permission.)

Remarkably, the negative predictive value of MRA for left main or three-vessel disease was 97% to 100%. A meta-analysis aggregating studies using different CMR sequences showed a subject-level sensitivity of 88% and a specificity of 56% for detection of coronary stenosis,¹²⁵ and a multicenter study using whole-heart 1.5-T CMR showed a subject-level sensitivity of 88% and a specificity of 72% for detection of coronary stenosis greater than 50%.¹²⁶

CCT has shown tremendous progress in the evaluation of native vessel coronary artery disease (Fig. 53-22). Systematic review of studies using 64-slice technology, the current standard, shows a sensitivity of 97% (range, 94-99) and a specificity of 88% (range, 79-97), which is better than that of CMR coronary angiography.¹²⁷ This accuracy was confirmed in recent large studies.^{128,129} Epicardial coronary calcium is associated with the development of coronary atherosclerosis and is a marker of increased risk for adverse events associated with coronary artery disease,¹³⁰ whereas the absence of any significant calcification is associated with a very low risk of future cardiovascular events.¹³¹ The presence of epicardial calcium is a well-recognized limitation for coronary artery CCT, with an exaggerated appearance on imaging (frequently referred to as *blooming*) that interferes with the accurate determination of coronary artery stenosis.¹³²

Available data suggest coronary CMR to be superior to CCT in patients with increased epicardial calcium.¹³³

CCT and CMR are suited for graft vessel disease because accuracy is generally higher than 90%.¹³⁴ Accuracy is superior to that for the detection of native vessel disease because the grafts are larger and move less, thus reducing the technical demands of imaging. However, local image artifacts caused by associated implanted metallic objects (such as hemostatic clips, stainless steel graft markers, and sternal wires) may interfere with adequate graft visualization, causing signal dropout with CMR and beam-hardening artifacts with CCT (Fig. 53-23).¹²⁴ Technical improvement has been achieved with the use of the appropriate CMR sequences.^{135,136}

There are growing data regarding the determination of prognosis in patients with coronary atherosclerosis or obstructive disease. Coronary artery calcification, most commonly quantified with the Agatston score, is predictive of future coronary adverse events and is superior to traditional risk factors alone,^{130,131,137} and it has been proposed as a supplementary stratification tool for assessment of cardiovascular risk.¹³⁸ CCT also has prognostic information: patients with obstructive disease have a worse prognosis compared with those with nonobstructive or no disease, which further worsens with the number of vessels involved.¹³⁹ CT angiography composite scores

FIGURE 53-22 ■ Coronary artery disease. **A**, Curved multiplanar reformation cardiovascular computed tomographic image of the left anterior descending coronary artery shows a calcified plaque (arrow) without stenosis. **B**, Invasive radiographic angiography confirmed the absence of stenosis, with the plaque present as a subtle indentation of the lumen (arrow). **C**, Curved multiplanar reformation cardiovascular computed tomographic image of the right coronary artery showing a noncalcified plaque with severe stenosis (arrow). **D**, Invasive radiographic angiography confirmed the presence of severe stenosis (arrow).

FIGURE 53-23 ■ **A**, A three-dimensional volume-rendered cardiovascular computed tomographic image of a left internal mammary graft to the left anterior descending coronary artery (white arrow) and a reverse saphenous vein graft to an obtuse marginal graft (black arrow). Note the stents in the native coronary vessels (arrowheads). **B**, Curved multiplanar cardiovascular computed tomographic image of the left internal mammary graft to the left anterior descending coronary artery in the same patient, demonstrating multiple surgical clips (arrowheads).

including plaque burden have been proposed for further prognostic improvement.¹⁴⁰

THE FUTURE ROLE OF CMR AND CCT

CMR and CCT technologies continue to evolve both in hardware and software improvements. Advances in CCT have shifted from increasing the number of detectors to algorithms aiming to decrease radiation exposure and to enhance tissue characterization and functional information. Advances in CMR have been focused on higher field strengths, faster imaging, and novel contrast agents. Both technologies are likely to continue to advance quite rapidly with their clinical roles defined by multicenter trials.

INTRODUCTION TO NUCLEAR CARDIOLOGY

Nuclear cardiology involves the imaging of cardiac radio-pharmaceutical distribution to characterize physiologic and pathophysiologic processes in the heart. The ability to image myocardial perfusion, function, and metabolism noninvasively with nuclear techniques has led to the development of a field that has been validated extensively and provides powerful diagnostic and prognostic information in the management of patients with known or suspected coronary artery disease (CAD). Moreover, nuclear cardiology procedures have been used widely in the evaluation of patients before cardiac and noncardiac surgery. This chapter provides an overview of the concepts and techniques used in nuclear cardiology and

summarizes its role in the assessment of patients with stable coronary disease and acute coronary syndromes and in the determination of myocardial viability in patients considered for revascularization. A complete discussion of the technical and procedural aspects of nuclear cardiology is beyond the scope of this chapter; therefore, the central focus will be on the use of nuclear cardiology in patients with known or suspected CAD, with an emphasis on patients undergoing cardiac surgery. For a more detailed discussion, the reader is referred to other more comprehensive reviews.^{1,2}

General Principles

Nuclear cardiology has been dominated by radionuclide myocardial perfusion imaging (MPI) as a means to evaluate patients with known or suspected coronary disease.

MPI is performed for diagnostic evaluation of patients with symptoms suggestive of myocardial ischemia and for risk stratification of patients with known CAD. Radionuclide MPI plays a central role in the evaluation of the cardiac patient, and it is in widespread clinical use, with more than 7 million MPI procedures performed in the United States annually.³

Myocardial perfusion is governed during resting conditions by the coronary resistance vessels. During periods of increased work, such as during exercise, flow is increased to balance the metabolic demands of the myocardium. This is achieved by vasodilation of resistance vessels, which reduces vascular resistance in the coronary arterial bed. In stenotic, atherosclerotic coronary arteries, resting flow is maintained by decreasing downstream vascular resistance. Although this compensation maintains flow under resting conditions, a critical stenosis (>50% to 70% narrowing of the lumen) impairs coronary flow reserve or the ability of the artery to increase flow appropriately during periods of increased demand.

Radioactive Tracers

Myocardial perfusion is imaged with the use of radiopharmaceuticals that accumulate rapidly in the myocardium in proportion to myocardial blood flow. The most commonly used radiotracers currently are the ^{99m}Tc-labeled compounds sestamibi and tetrofosmin and, to a lesser extent, thallium (²⁰¹Tl). When injected intravenously, these tracers are extracted from the blood pool and accumulate in cells, including myocytes, which have an intact cell membrane and are metabolically active. ^{99m}Tc-sestamibi and tetrofosmin are lipophilic cationic complexes that are taken up by myocytes across mitochondrial membranes, but at equilibrium are retained within the mitochondria because of a large negative transmembrane potential. ²⁰¹Tl is transported like potassium across the myocyte sarcolemmal membrane, via the Na-K adenosine triphosphatase transport system. Because the retention of radiotracer is proportional to myocardial flow, the amount of tracer uptake is a surrogate visualized representation of regional myocardial perfusion. The tracers used are radioactive isotopes that undergo radioactive decay over a short period of time.

Equipment and Procedures

As the accumulated radiotracer decays, photons are emitted that exit the body and can be detected using a specialized gamma camera. MPI uses single photon emission computed tomography (SPECT) techniques to acquire and ultimately display the perfusion distribution obtained from the radiotracer uptake. After the radiopharmaceutical is injected, the patient lies supine on the SPECT camera table and is positioned in the gantry of the camera. The photons emitted from the heart are then detected via large crystals or solid state detectors in the SPECT camera as it revolves around the patient.

As the camera detector moves around the patient, emitted photons interact with the camera's crystal and produce scintillations of light that represent the spatial

distribution of radioactivity in the patient. The emitted "counts" localized to each region of the myocardium are then stored digitally. This three-dimensional representation of the myocardial perfusion is then processed and reconstructed using computer algorithms to display the acquired information in a series of slices, oriented in the short axis and the horizontal and vertical long axes of the left ventricle. The slices are then displayed on a computer screen for visual inspection of regional myocardial perfusion and computer quantification of tracer uptake. The stress images, acquired after injection of radiotracer during exercise or pharmacologic stress (described later in detail) are displayed adjacent to images acquired at rest, permitting direct comparison of perfusion in the two imaging states. The maximum uptake of radiotracer in the heart is used to represent normal perfusion, and the rest of the counts are considered as relative uptake to this maximum. As shown in Figure 54-1, a regional perfusion defect on the stress images that is not present on the resting study is considered to be *reversible* and consistent with stress-induced ischemia in that vascular territory. A defect that persists on stress and rest is deemed *fixed* and representative of scar from prior myocardial infarction. Quantitative programs are commonly used to assess the extent and severity of each defect, which is then incorporated into the final interpretation of regional myocardial perfusion. The perfusion images are also obtained in concert with electrocardiographic (ECG) gating, which stores the counts with respect to the timing of the cardiac cycle. By gating the acquisition to the R-R interval of the ECG, images from each frame can be summed and displayed as a cine movie of the left ventricle contracting from diastole to systole. Performing gated SPECT facilitates measurement of left ventricular ejection fraction (LVEF) and left ventricle (LV) volumes by automated computer algorithms, as well as visual inspection of the movie for regional wall motion and thickening (Fig. 54-2).⁴

A typical SPECT MPI protocol involves the performance of exercise, typically on a treadmill or bicycle, or with a pharmacologic stressor, such as adenosine, dipyridamole, regadenoson, or dobutamine in patients who are unable to perform physical exercise. The radiotracer is injected at peak stress and the stressor is then continued for an additional 1 to 2 minutes to maximize myocardial extraction of the circulating tracer. Imaging is performed 30 to 60 minutes later for sestamibi or tetrofosmin, because these agents have only minimal redistribution, or washout from the myocardium. The initial imaging can be either at rest or at stress, and both studies can be performed on the same day depending on the patient's weight. While ²⁰¹Tl is used less commonly for stress MPI, it can be used for rest imaging in a "dual isotope" protocol. In this protocol ²⁰¹Tl is injected for resting imaging, which is then followed immediately by stress perfusion imaging with ^{99m}Tc agent, thus obviating the need to wait 2 to 3 hours for the first dose to decay.⁵ As such, imaging time is reduced and patient throughput is increased; however, the radiation dose the patient receives is greater. Recent advances in camera technology and processing have facilitated faster image acquisition and the use of lower doses of radiopharmaceuticals.

FIGURE 54-1 ■ Visual display of single photon emission computed tomography (SPECT) myocardial perfusion images. The stress study (rows labeled A) is shown immediately above the rest study (rows labeled B) for comparison. There are three representations of the same imaging procedure, each oriented differently: short-axis slices from apex to mid-ventricle and mid-ventricle to base (*top*), vertical long-axis slices from septum to lateral wall (*middle*), and horizontal long-axis slices from inferior to anterior wall (*bottom*). **A**, Normal study in grayscale, with uniform uptake of radiotracer on stress and rest. **B**, Color-enhanced study in which the stress images demonstrate a perfusion defect in the anterolateral wall, as evidenced by less radiotracer accumulation relative to other regions of the left ventricle. As the corresponding rest images show normal perfusion throughout the myocardium, the perfusion defect is considered “reversible,” consistent with ischemia. **C**, These SPECT images demonstrate large perfusion defects in the anteroapical, inferoseptal, and apical regions, which are present on both the stress and rest images. Because these defects do not show any change from stress to rest, they are termed *fixed defects*, consistent with scar (i.e., prior myocardial infarction).

STABLE CORONARY ARTERY DISEASE (DIAGNOSIS AND RISK STRATIFICATION)

Stress Testing in the Detection of Coronary Artery Disease

Nuclear cardiology is a central part of the evaluation of patients with suspected or proven coronary artery disease. The ability of SPECT myocardial perfusion imaging to detect CAD in patients with symptoms suggestive of ischemic heart disease has been validated extensively.

Exercise Stress Testing

Exercise stress testing without adjunct noninvasive imaging is frequently used as the initial screening test in patients without known coronary artery disease who have chest pain syndromes or symptoms suggestive of ischemia. The premise of exercise stress testing is that the increased myocardial oxygen demand during exercise will produce clinical signs of ischemia (e.g., angina, ECG changes) in the setting of a flow-limiting stenosis that impairs myocardial blood supply. The diagnostic performance of this test varies greatly depending on the pretest likelihood of the population being studied. In patients with an intermediate pretest probability of CAD on the basis of symptoms and risk factors, exercise treadmill testing is useful as an initial screening test. However, the overall sensitivity of treadmill exercise testing is approximately 70%. A meta-analysis of more than 24,000 patients undergoing exercise stress testing and coronary angiography observed a mean sensitivity on 68% and a mean specificity of 77%. Accuracy was greatest in patients with

multivessel coronary disease and those with left main or three vessel coronary artery disease.⁶

Exercise Stress Myocardial Perfusion Imaging

Exercise treadmill testing relies on changes in the 12-lead ECG as a surrogate of ischemia, rendering the accuracy of the test highly dependent on the baseline electrocardiogram. Abnormalities, such as previous myocardial infarction (Q waves or left bundle branch block) or ST-T wave changes owing to left ventricular hypertrophy or therapy with digoxin, hamper the ability to interpret ischemic changes accurately during exercise. In patients with an abnormal ECG, myocardial perfusion imaging adds significant diagnostic accuracy to the treadmill test for detecting coronary artery disease. Large studies have consistently shown that SPECT myocardial perfusion imaging with technetium-labeled agents, such as sestamibi, yields a greater than 90% sensitivity for the detection of coronary artery disease.⁷⁻⁹ False-negative scans tend to occur in the setting of single-vessel disease, particularly in the left circumflex artery distribution, with a mild degree of stenosis (<70%), or when the patient is unable to achieve the target heart rate or is taking anti-anginal therapy. These studies have also observed that the specificity of stress SPECT imaging is in the range of 68%. The less optimal specificity can be attributed to referral bias (performing angiography in only those patients with abnormal scans) and false-positive scans with defects resulting from artifacts produced by soft tissue attenuation (diaphragm, breast) or patient motion. Contemporary imaging techniques that use ECG-gating have facilitated the simultaneous assessment of myocardial perfusion and function. Examination of regional wall

FIGURE 54-2 ■ Gated single photon emission computed tomography (SPECT) still-frame images of diastole and systole. During SPECT image acquisition, the acquired images can be stored in relationship to the cardiac cycle using the R-R interval of the electrocardiogram. The resulting images that are "gated" to the cardiac cycle can then be viewed as a cine-loop from diastole to systole. Moreover, these data can be used to calculate left ventricular (LV) volumes during diastole and systole, as well as the corresponding left ventricular ejection fraction (diastole-systole).

motion and thickening enhances the evaluation of a suspect area of hypoperfusion by providing the ability to distinguish true myocardial scarring from attenuation. Specificity can also be enhanced with the use of attenuation correction. These algorithms incorporate additional data obtained from an external radioactive source or computed tomography to create a soft tissue attenuation image of the chest and then to adjust the regional counts

on the emission scan to correct for the loss of counts because of attenuation from overlying breast, diaphragm, and chest wall structures.¹⁰

Stress-Only Imaging

For patients who have normal stress imaging, rest imaging can result in increased patient inconvenience, radiation exposure, laboratory inefficiency, and cost.¹¹ As a result, stress-only imaging protocols have been examined. A study of 460 stress-rest technetium myocardial perfusion studies noted that in 20% of studies, the stress images were completely normal and that the addition of rest images added no additional information.¹² In addition to reduced radiation exposure and patient cost, stress-only imaging has been verified from a prognostic standpoint as well, with follow-up studies of patients with normal stress-only studies demonstrating a less than 1% annualized cardiac event rate.¹³

Pharmacologic Stress Myocardial Perfusion Imaging

Many patients are unable to perform physical exercise to a workload adequate for a diagnostic exercise stress test; therefore, myocardial perfusion imaging performed after pharmacologic stress is used frequently as an alternative. This imaging is typically performed after the intravenous infusion of a vasodilator, such as dipyridamole, adenosine, or regadenoson, or after administration of the inotropic dobutamine. Dipyridamole stimulates the release of endogenous adenosine in the distal coronary vasculature, which then binds adenosine receptors in the vasculature, producing the desired effect of coronary artery vasodilation and undesirable effects such as flushing, bronchospasm, headache, and transient heart block. This vasodilation of the resistance vessels increases myocardial blood flow, mimicking the effects of physical exercise. Dipyridamole is typically administered intravenously as a bolus injection over 4 minutes with peak effect occurring at 8 minutes, at which time the radiotracer is injected.¹⁴ A 4- to 6-minute continuous infusion of intravenous adenosine is now used more commonly.^{15,16} Both agents are equally effective in increasing myocardial blood flow threefold to fivefold over rest, which is similar to that produced by exercise; however, adenosine tends to achieve maximal flow in more patients than dipyridamole does, and side effects are more common with adenosine. Regadenoson is an adenosine A2a receptor agonist that selectively increases coronary blood flow without producing side effects, such as hypotension, AV block, chest pain and flushing, which are common with adenosine and dipyridamole.¹⁷⁻¹⁹ Regadenoson can be used as an alternative stressor in patients with lung disease, because its receptor selectivity helps to avoid bronchospasm that can occur with the other vasodilators.^{20,21}

An intravenous infusion of dobutamine is also effective for pharmacologic stress. It is typically used as an alternative to vasodilator stress in patients with bronchospasm and pulmonary disease. The dobutamine infusion produces increased myocardial oxygen demand by increasing heart rate, blood pressure, and myocardial contractility.²²

All the currently used pharmacologic stress agents have similar ability to produce flow heterogeneity and corresponding perfusion defects in the presence of a significant (>50% to 70%) stenosis of a coronary artery. A meta-analysis of dipyridamole SPECT imaging demonstrated a sensitivity of 89% and specificity of 65% for the detection of coronary artery disease. Dipyridamole and adenosine tests had essentially similar sensitivities and specificities. The sensitivity of dobutamine SPECT imaging to detect CAD is approximately 80%, which is slightly lower than the vasodilator agents.²³

Pharmacologic Stress and Low-Level Exercise Combination

Failure to achieve target heart rates during exercise MPI tests decreases the sensitivity to diagnose coronary artery disease. Studies have shown that combined exercise and adenosine infusion approach was well tolerated and resulted in the detection of a greater amount of myocardial ischemia on MPI, while also allowing for the assessment of functional capacity.²⁴

A study of patients who underwent a combination of exercise and pharmacologic stress not only felt better than those who only underwent pharmacologic stress; they also had better image quality in terms of target-to-background ratio. This combination approach may be useful in patients undergoing MPI who are unlikely to achieve a goal heart rate.²⁴

Prognosis and Risk Stratification

Stable Angina

The goals of stress testing extend beyond the detection of coronary artery disease alone. For stress testing information to be useful, results must reliably identify patients of sufficiently low risk that further evaluation or intervention can be safely avoided, while also providing additional information to the clinical risk assessment when results are abnormal. The ability of exercise and pharmacologic MPI to add incremental prognostic information to the clinical risk assessment in patients with known CAD has been evaluated in thousands of patients.²⁵ Several large studies of patients with known or suspected CAD, including both men and women, have demonstrated the incremental prognostic value of a normal MPI.²⁶⁻³⁰ Perhaps of greatest clinical utility is that these studies have consistently shown that patients with normal MPI have a subsequent annual rate of cardiac death and nonfatal myocardial infarction (MI) of less than 1%, even in patients with known CAD.^{31,32} When the results are abnormal, the SPECT scan provides incremental prognostic information beyond that obtained by clinical, ECG, and stress testing combined. Moreover, the value of SPECT MPI in determining prognosis is such that the information obtained from subsequent coronary angiography does not provide any incremental prognostic information beyond that obtained by the SPECT results.^{33,34} The increase in the risk of hard events increases in proportion to the severity and extent of the perfusion defect when assessed by semiquantitative methods or automated

quantitative approaches. The degree of ischemia on SPECT is associated with an increase in the short-term incidence of nonfatal MI, whereas scar size is more predictive of cardiac death.³² Important stress MPI variables that are predictive of future cardiac events include defects in more than 1 vascular territory (multivessel disease), transient left ventricular cavity dilation during stress,³⁵ and increased pulmonary uptake of radiotracer^{36,37} (suggesting increased LV filling pressures), as well as other parameters outlined in [Box 54-1](#). The prognostic ability of stress MPI is also enhanced by inclusion of ECG-gated SPECT, which permits assessment of left ventricular global systolic performance, the most potent predictor of event-free survival, as well as analysis of regional wall motion and left ventricular volumes.³⁸⁻⁴⁰

Medical Therapy versus Revascularization

One of the most important contributions of stress MPI in the clinical evaluation of patients with known or suspected CAD is the ability to provide prognostic information that can be used to guide further testing and therapies. Because the extent and severity of ischemia on a stress MPI study is directly proportional to the risk of future cardiac events, this information can be incorporated into the decision-making process concerning medical or revascularization therapies for a given patient. Patients with mild ischemic defects that are not high risk generally can be safely treated medically, whereas high-risk findings (e.g., transient ischemic dilation, multivessel disease pattern, large territory at risk) should be strongly considered for more invasive evaluation with a lower threshold for revascularization. A 3-year follow-up study of patients with mild to moderate defects on stress SPECT myocardial perfusion imaging treated with medical therapy noted a 2% incidence of cardiac death or nonfatal infarction and a less than 5% rate of revascularization, suggesting that SPECT imaging is highly useful in selecting patients with CAD at a sufficiently low risk for events

BOX 54-1 Stress Testing Variables Associated with Worse Prognosis

PERFUSION PARAMETERS

- Multivessel disease pattern
- Large reversible (ischemic) defect
- Large scar, >14% of left ventricle
- Transient left ventricular dilation with stress
- Right ventricular uptake
- Resting left ventricular dysfunction
- Pulmonary uptake of ²⁰¹Tl

NONPERFUSION PARAMETERS

- Poor exercise capacity
- Angina at low workload
- Dynamic ST-segment depression ≥ 3 mm with exercise
- Exercise-induced ventricular arrhythmias
- Vasodilator stress-induced ST-segment depression ≥ 1 mm
- Hypotensive blood pressure response

such that revascularization is not necessary.⁴¹ In contrast, the benefit of revascularization over medical therapy has been characterized in patients with high-risk stress SPECT MPI findings. Hachamovitch and colleagues³² followed 5183 patients after stress MPI for a mean of 2 years; they found that the rates of MI and cardiac death did not differ substantially from patients treated with medical therapy or revascularization after a normal or mildly abnormal scan. However, patients with severely abnormal scans had significantly higher annualized cardiac death rate when treated medically (4.6% per year) compared to those referred for revascularization (1.3% per year; Fig. 54-3). Patients with a greater ischemic burden on imaging were also found to benefit more from revascularization than from medical therapy, with serial imaging studies showing a greater reduction in reversible defect size in those treated with revascularization. A subsequent observational study of 10,627 consecutive patients with no prior infarct or revascularization demonstrated a survival advantage in patients with no or mild ischemia treated with medical therapy versus medical therapy, with revascularization having prognostic benefit beyond medical therapy in patients with moderate to severe ischemia.⁴² The Clinical Outcomes Utilizing Revascularization and Aggressive Drug Evaluation (COURAGE) trial⁴³ showed no difference in the incidence of death or myocardial infarction in 2287 with stable angina randomized to optimal medical therapy or percutaneous revascularization. A substudy of this trial showed that the addition of percutaneous revascularization to optimal medical therapy resulted in more effective reduction of ischemia than medical therapy alone, with less angina.⁴⁴ Moreover, regardless of treatment assignment, the degree of residual ischemia on follow-up perfusion imaging was proportional to the risk of subsequent cardiac events. More recently, the Bypass Angioplasty Revascularization Investigation 2 Diabetes Trial (BARI 2D) was completed in search of the optimal treatment for diabetic patients with stable ischemic heart disease. The two groups compared were prompt revascularization therapy with intensive medical therapy versus intensive medical therapy alone. At 5 years, there was no significant difference in the rates of death and major cardiovascular events between the two groups.⁴⁵ In the COURAGE and BARI 2D trials, the decision of revascularization or intensive medical therapy was made after cardiac catheterization. Based on these studies, it appears that revascularization can be used selectively in patients with CAD based on the extent and severity of the ischemic burden. Patients with low-risk findings can be treated medically, whereas extensive ischemia is best treated with more aggressive interventions.

The International Study of Comparative Health Effectiveness with Medical and Invasive Approaches (ISCHEMIA) trial is an ongoing trial comparing revascularization and optimal medical therapy against optimal medical therapy alone before cardiac catheterization in a group of higher-risk patients with stable ischemic heart disease.

These principles have been shown to have favorable effects in terms of patient outcomes and cost when applied clinically. Several large studies have focused on

FIGURE 54-3 ■ Single photon emission computed tomography (SPECT) myocardial perfusion imaging and prognosis. This large retrospective analysis of patients undergoing stress SPECT myocardial perfusion imaging demonstrates the incremental prognostic information obtained with the imaging results. The annualized incidence of cardiac death (**A**) and myocardial infarction (MI) (**B**) is displayed for patients treated medically (solid columns) and for those undergoing revascularization (gray columns) with respect to the myocardial perfusion image result. Annualized cardiac events were low (<1%) in both groups with normal SPECT studies. However, event rates increased with respect to the degree of SPECT abnormality. Survival was significantly improved in those with severely abnormal scans who underwent revascularization. * $P < 0.01$ compared with patients undergoing revascularization early after nuclear testing; † $P < 0.001$ compared with patients treated with medical therapy after nuclear testing. *Abnl*, Abnormal; *NI*, normal. (Reprinted with permission from Hachamovitch R, Berman DS, Shaw LJ, et al: Incremental prognostic value of myocardial perfusion single photon emission computed tomography for the prediction of cardiac death: differential stratification for risk of cardiac death and myocardial infarction. *Circulation* 97:535–543, 1998.)

the clinical use of stress MPI to guide patient management, and they have shown that referral for coronary angiography is accordingly low ($\approx 3.5\%$) after a normal stress MPI, but increases to 60% when the stress MPI is moderately to severely abnormal.^{32,46,47} This finding demonstrates that clinicians can incorporate MPI into their practice appropriately, particularly when deferring further invasive evaluation when the MPI is normal. The use of stress MPI to guide patient management has also been demonstrated to be cost-effective. An “ischemia-guided” approach to managing patients with CAD has been shown to optimize the use of angiography and

subsequent revascularization procedures.⁴⁸ The Economics of Noninvasive Diagnosis study^{49,50} compared differences in cost in 11,372 consecutive patients referred for either stress MPI or cardiac catheterization as the initial approach. The rates of subsequent myocardial infarction were the same in the two groups, and costs were significantly higher for the direct cardiac catheterization group as compared with the MPI ischemia-guided approach. Moreover, patients sent directly to cardiac catheterization were more likely to be treated with coronary revascularization in all subsets of risk when compared with those undergoing stress MPI initially. The ischemia-guided approach to stable angina was found to be less costly, with fewer interventions and similar cardiac event rates. These cost differences can be attributed directly to a decrease in apparent unnecessary procedures in patients with negative MPI results.

Preoperative Evaluation for Noncardiac Surgery

Perioperative cardiac events are an important cause of morbidity and mortality during and after noncardiac surgery, and they occur in more than 2% of patients undergoing these procedures. Much of this risk can be assessed preoperatively with clinical evaluation using the Revised Cardiac Risk Index (e.g., history of coronary artery or cerebrovascular disease, congestive heart failure, renal insufficiency, diabetes requiring insulin, high-risk surgical procedure) to identify patients at high risk for cardiac complications who might benefit from risk-reduction strategies (i.e., specific perioperative medical therapy or revascularization) and subjects of sufficiently low risk for whom further evaluation before surgery is not necessary.⁵¹ However, patients with an intermediate risk for cardiac complications may benefit from further noninvasive testing to identify ischemia and provide further risk stratification before surgery.⁵² Provocative testing for ischemia is typically performed for such patients; however, exercise testing is not always feasible in patients with pulmonary disease or low exercise capacity, and in particular those undergoing orthopedic or vascular surgery. Pharmacologic stress MPI has been shown to add significant information to preoperative risk stratification⁵³; it is recommended for patients with intermediate clinical risk predictors (e.g., prior MI, diabetes, renal insufficiency) who have poor functional capacity or those undergoing a high-risk surgical procedure (e.g., emergent surgery, aortic or peripheral vascular surgery, prolonged procedures with anticipated large blood loss or volume shifts). When results of stress MPI are normal, the incidence of perioperative cardiac events has been shown to be approximately 1% for all procedures, including major vascular surgery.⁵⁴ Although the severity and extent of ischemia remains an important predictor of adverse cardiac events during and after surgery, recent studies have shown that revascularization before noncardiac surgery does not appear to affect outcome in terms of death and nonfatal myocardial infarction.⁵⁵ As such, the 2014 ACC/AHA guidelines now recommend nuclear stress imaging selectively in patients with a high clinical risk of perioperative cardiac events.

ACUTE CORONARY SYNDROMES

Territory at Risk and Infarct Size

Resting MPI has been used to determine the territory at risk during an acute coronary syndrome, and it can be used to assess the extent of myocardial salvage achieved with reperfusion strategies.⁵⁶ Tc-99m-labeled radiopharmaceuticals can be injected at rest in the setting of an acute ST-segment elevation myocardial infarction upon presentation. After initial treatment and stabilization with either pharmacologic or mechanical reperfusion, perfusion images can be acquired that represent the initial myocardial area at risk during the coronary occlusion. These images are then compared to those acquired at rest after a subsequent injection after reperfusion. The difference in the size of the defect on these two scans is the *salvage index* (initial territory at risk-to-ultimate scar, which represents the degree of myocardium that was rescued by reperfusion).^{57,58} This methodology is not used widely in clinical practice, but it is a useful tool in the evaluation of therapies used in the treatment of acute myocardial infarction. The salvage index has been validated as a surrogate marker of patient outcome, and provides a quantitative means to compare the efficacy of therapeutic strategies.⁵⁹ The use of the infarct size, territory at risk, and the salvage index has played a central role in trials focusing on the efficacy of angioplasty^{57,60} and thrombolysis.⁶¹ This methodology can also assist in determining important clinical factors associated with reperfusion outcome such as time to reperfusion.⁶⁰

Myocardial infarct size can be measured quantitatively after MI and has been shown to be highly predictive of poor outcome.^{58,59,62,63} The ischemic burden on cardiac stress SPECT imaging is associated with future nonfatal myocardial infarction, whereas fixed perfusion defects and a depressed ejection fraction are predictive of future cardiac death.⁶⁴ Quantification of the infarct size as a percentage of the left ventricle is effective to risk stratify a patient's risk for cardiac death over the near term. Studies using Tc-99m SPECT after acute myocardial infarction have observed that mortality within the subsequent 24 months is approximately 8% if the infarct encompasses more than 12% to 14% of the left ventricle.^{63,65}

Rest Myocardial Perfusion Imaging for Acute Coronary Syndrome

The triage of patients presenting to the emergency department with acute chest pain is a substantial diagnostic challenge. Radionuclide myocardial perfusion imaging has been shown to have favorable diagnostic and prognostic value in this setting, with an excellent sensitivity to detect acute myocardial infarction that is not recognized by other testing modalities (i.e., serum markers, ECG).⁶⁶⁻⁷⁰ A major advantage of a triage protocol that uses rest SPECT MPI is that ischemia and infarction can be detected earlier than with serum markers. A patient with chest pain and an ECG that is normal or nondiagnostic for ischemia or infarction can receive an injection

in the emergency department and then be imaged within 30 to 60 minutes. Several observational and randomized studies have repeatedly shown that a normal resting perfusion imaging study has a negative predictive value greater than 99% to exclude myocardial infarction and that defects at rest are associated with a higher incidence of death and MI at 30 days.⁶⁹⁻⁷² A recent trial by Lim and colleagues⁷³ examined whether the addition of stress MPI to the standard emergency department evaluation of chest pain would improve decision making in terms of hospital admissions or subsequent cardiac events. In this trial, patients were observed in the emergency department for 6 hours with serial ECGs and cardiac marker evaluations. If results of their 6-hour stay was negative, they were randomized to either standard emergency department care or stress MPI. Findings of this study showed that patients in the stress MPI group had an 8% lower rate compared with those in the clinical assessment only group and no difference in the risk of cardiac events at 30 days.⁷³ As such, a normal resting MPI in a patient with chest pain essentially excludes acute MI (AMI) and is predictive of a sufficiently low risk of near-term adverse cardiac events that the patient can be discharged home. Alternatively, an abnormal study is associated with a worse near-term outcome, and hospitalization is warranted (Fig. 54-4). Once MI or unstable angina are excluded, provocative testing can be performed, with or without MPI, to identify stress-induced ischemia. Protocols that use immediate rest MPI to exclude an acute coronary syndrome and subsequent stress testing to evaluate for significant CAD have demonstrated both reductions in unnecessary hospitalizations and cost savings compared with routine care.⁷⁴

Postmyocardial Infarction Risk Stratification

Stress MPI has been shown to have excellent diagnostic value in patients after an AMI. Dipyridamole vasodilator stress MPI early after AMI is highly predictive of future cardiac events. In fact, recent studies have found that the most important predictors of future cardiac death and recurrent myocardial infarction are the extent and severity of degree of the reversible (ischemic) myocardial perfusion defect. Bateman and colleagues⁷⁵ reported the results of a multicenter trial that randomized 451 patients after a first AMI to either early (hospital days 2 to 4) dipyridamole stress MPI or routine predischarge (hospital days 6 to 12) submaximal exercise MPI. The extent and severity of the stress defect and the degree of defect reversibility were found to be the most important predictors of cardiac death and recurrent myocardial infarction. The early use of pharmacologic stress perfusion imaging after acute infarction was more predictive of early and late cardiac events, and provided greater incremental diagnostic and prognostic value than predischarge submaximal exercise perfusion imaging. One major advantage of this approach is that management decisions can be made much earlier in the hospital course after an uncomplicated acute myocardial infarction. More recently, the INSPIRE trial showed that MPI performed early after AMI in appropriate patients can safely and reliably identify patients with low-risk findings or lack of inducible ischemia who would be unlikely to benefit from an invasive approach as well as those with extensive ischemia in whom intensive anti-ischemic medical or interventional therapies are appropriate. As such, noninvasive

FIGURE 54-4 ■ Rest single photon emission computed tomography myocardial perfusion imaging during ongoing chest pain in a patient with a normal electrocardiogram. Injection of radiotracer during ongoing chest pain and subsequent imaging 45 minutes later demonstrates a moderate-sized area of decreased perfusion in the inferior wall. The patient was brought directly to cardiac catheterization, and coronary angiography demonstrated a 95% stenosis of the right coronary artery that was treated with angioplasty and intracoronary stenting.

imaging as an initial strategy for categorizing risk and triaging subsequent care in stable survivors of myocardial infarction who have not undergone acute coronary angiography seems reasonable.⁷⁶

ASSESSMENT OF MYOCARDIAL VIABILITY

Left Ventricular Ejection Fraction and Prognosis

Numerous studies have demonstrated that left ventricular systolic performance is a powerful and independent predictor of mortality in patients both with and without coronary artery disease. When the LVEF becomes depressed after MI or with chronic ischemic heart disease, the risk of sudden cardiac death increases substantially.^{38,77-79}

Data from the Thrombolysis in Myocardial Infarction trials indicated that the prognostic significance of LVEF assessment was also maintained after thrombolysis, although the overall mortality was lower than in the pre-thrombolytic era.⁸⁰ The powerful prognostic significance of resting LVEF assessed by radionuclide angiography is also important in patients treated with thrombolysis or primary angioplasty.^{77,81} Resting LVEF is not only the strongest predictor of 6-month mortality; it is also predictive of ventricular arrhythmias and sudden death in a similar group of patients. The prognostic significance of LVEF in patients with chronic coronary artery disease is also well established and is independent of the extent of anatomic disease.⁸²

All the available techniques used to assess left ventricular function, including nuclear techniques such as radionuclide angiography and gated-SPECT, as well as two and three-dimensional echocardiography, contrast ventriculography, and magnetic resonance imaging, can provide similar prognostic information in patients with myocardial infarction and chronic CAD. Radionuclide angiography is a highly accurate, widely validated, and reproducible technique, making it a useful tool when serial measurements of LVEF are required. However, the more widespread use of two-dimensional resting echocardiography, gated-SPECT MPI and MRI has led to these modalities replacing radionuclide angiography for the assessment of LVEF. Ejection fraction assessed during gated-SPECT stress MPI provides incremental prognostic information beyond the perfusion imaging results. In a study of 1680 patients undergoing stress MPI, patients with a gated SPECT LVEF $\geq 45\%$ had low mortality rates ($<1\%$ per year), even when associated with severe perfusion defects. However, patients with an LVEF $< 45\%$ on gated SPECT had a mortality rate of 9.2% per year, even if only mild to moderate perfusion abnormalities were present.⁸³ This finding underscores the importance of LVEF in determining prognosis, and the need to pursue aggressive medical and surgical strategies in patients with depressed LVEF. Gated SPECT indices of end-diastolic and end-systolic volumes consistent with left ventricular dilation have also been shown to add prognostic value in predicting cardiac death and nonfatal

myocardial infarction independent of the perfusion abnormalities on the scan.³⁸

PET and SPECT in Determining Myocardial Viability

Left ventricular ejection fraction is a major determinant of survival in patients with ischemic heart disease. As a result, therapeutic strategies that can improve systolic performance and thereby improve survival have been widely studied. Patients with chronic coronary artery disease and patients after acute myocardial infarction represent two important groups at risk for the development of left ventricular dysfunction. However, the left ventricular systolic dysfunction is not always due to scarring and fibrosis of the myocardium, and it may be the result of the repetitive or chronic myocardial ischemia. As such, left ventricular dysfunction at rest may not necessarily be irreversible. Thus, the evaluation of patients with ischemic cardiomyopathies because of chronic CAD or myocardial infarction becomes important to select which patients might have reversible dysfunction and potentially benefit from coronary revascularization.

Ischemic myocardial dysfunction can be produced by four pathophysiologic processes. After myocardial infarction, the myocardium within the vascular territory served by an acutely occluded culprit artery can undergo necrosis and scarring, leading to extensive fibrosis and subsequent regional dysfunction. With an acute coronary syndrome, if myocardial blood flow is restored either spontaneously or with a therapeutic reperfusion strategy such as angioplasty or thrombolysis, regional contractile dysfunction may occur even without myocardial necrosis, a state termed *stunning*. This postischemic dysfunction after a transient period of ischemia followed by reperfusion is characterized by normal flow but reduced function in the absence of myocardial scarring. Regional dysfunction can also be observed in chronic CAD, with reductions in blood flow presumably occurring more slowly. The contractile impairment is thought to be due to a compensatory downregulation of function during prolonged periods of myocardial hypoperfusion, a concept termed *hibernation*. Left ventricular dysfunction can also deteriorate because of remodeling, which is characterized by histologic and biochemical changes in the myocardium because of an ischemic insult.

Myocardial viability was initially defined as the ability to recover global or regional LV function after revascularization. In this paradigm, treatment of repetitive or chronic ischemia, defined pathologically as *stunning* and *hibernation*, respectively, was deemed responsible for the improvement in contractility. As such, the ability to identify dysfunctional but viable myocardium resulting from these pathologic states became important when considering a patient for potential revascularization.

Although recovery of function may be an important goal of revascularization, the central goal of assessing myocardial viability is to predict outcome with therapy—that is, to differentiate patients with potentially reversible left ventricular dysfunction whose prognosis might be improved with revascularization from those with large areas of infarct or scar who might not benefit (or even do

worse) with surgery. Thus, viability assessment provides better insight into the risk/benefit ratio in patients with ischemic left ventricular dysfunction by effectively stratifying those with a significant amount of viable myocardium who are at increased risk if treated medically from those who would be at high risk with either treatment.

Currently, there are a number of diagnostic approaches for assessing myocardial viability in patients with ischemic cardiomyopathy. The major nuclear cardiology modalities to determine viability include techniques that assess cell membrane integrity, regional perfusion, and myocardial metabolism.

Viability assessments are typically performed in a particular subset of patients, namely those with known coronary artery disease and left ventricular systolic dysfunction who are potential candidates for surgical revascularization. Most viability assessment is performed in patients with chronic ischemic cardiomyopathies or after acute myocardial infarction, because as many as 50% of patients with prior myocardial infarction will have residual viable myocardium.⁸⁴ The methods for viability assessment are similar to those used for prognostic assessment in patients with CAD. As such, protocols used for stress myocardial perfusion imaging can be easily modified to obtain information regarding viability. However, if the assessment of viability is the principal clinical question, a protocol designed to assess specifically viability should be used. In patients in whom the question of myocardial viability is primary, however, it is best to perform a specific viability imaging protocol. The nuclear cardiology techniques that have been validated extensively in the assessment of myocardial viability include the use of positron emission tomography (PET) imaging of myocardial metabolism, and resting SPECT perfusion imaging of ²⁰¹Tl and the ^{99m}Tc-labeled tracers sestamibi and tetrofosmin.

Positron Emission Tomography

Positron emission tomography (PET) has been evaluated extensively as a noninvasive imaging modality for viability assessment. PET viability studies involve the determination and comparison of both myocardial blood flow and the metabolic status of the myocardium.⁸⁵ Perfusion is usually assessed with ¹³N-labeled NH₃, and glucose utilization is typically assessed with ¹⁸F-fluorodeoxyglucose (FDG), which when taken up by the myocardium reflects glucose transport across the myocyte membrane. FDG accumulates in myocytes in proportion to glucose uptake, but undergoes phosphorylation by hexokinase to FDG-6-phosphate in the first step of glycolysis. FDG-6-phosphate is a form of deoxyglucose that becomes “trapped” in the myocyte and is not metabolized further. As such, FDG uptake reflects exogenous glucose utilization. Normal myocardium preferentially utilizes fatty acids for energy, but switches to increased glucose utilization during periods of ischemia. In myocardial regions with ischemic dysfunction, myocardial glucose uptake may be increased, and thus FDG uptake will be enhanced, reflecting viability. Conversely, FDG will not accumulate in areas of fibrosis or scar. FDG uptake is then compared with resting perfusion imaging. Perfusion-metabolism is considered “matched” if areas of preserved flow show

normal metabolic activity, and areas of reduced flow have diminished FDG uptake (scar); however, perfusion and metabolism may be discordant, or “mismatched.” In this scenario, FDG uptake will be present in areas of hypoperfusion, indicating that despite decreased blood flow, the myocardium is still metabolically active, hence viable. This mismatched defect is the most predictive of functional recovery after revascularization (Fig. 54-5).

Quantitative Methods. The clinical assessment of myocardial viability using FDG is based predominantly on comparison of its qualitative or semiquantitative uptake relative to a myocardial perfusion tracer. Quantification of myocardial glucose utilization is possible, but it requires kinetic modeling of transmembrane transport and phosphorylation to adjust for the behavior of injected FDG in relation to endogenous glucose.⁸⁶ A different quantitative approach is the assessment of myocardial glucose utilization, using dynamic PET acquisitions and sequential arterial blood sampling to measure fractional FDG uptake in relation to the delivered dose.

Perhaps of greater importance is the ability of cardiac PET to determine absolute myocardial blood flow using tracer kinetic models. Quantitative myocardial blood flow can be measured with dynamic imaging of ¹³N-ammonia, ⁸²Rb, or H₂¹⁵O. These agents can be used to determine regional myocardial blood flow. Flow can be measured at rest and after pharmacologic vasodilation to determine the myocardial blood flow reserve (ratio of maximal flow to resting flow). Reduction in coronary flow reserve has proved useful in the assessment of stenosis severity (flow limitation) in CAD,⁸⁷⁻⁹⁰ in patients with no known CAD but with risk factors,⁹¹ and to evaluate changes in flow after medical treatment of such CAD risk factors as hyperlipidemia,^{92,93} diabetes,⁹⁴ and smoking.⁹⁵

Flow reserve is also useful in differentiating viable from nonviable myocardium, because a certain degree of myocardial blood flow is necessary to maintain myocyte viability. In the setting of a functionally significant coronary artery stenosis, the vasculature distal to the lesion may retain the ability to vasodilate and thus increase regional myocardial blood flow. As such, regions of myocardium that can achieve this must therefore be viable. Flow reserve has been studied as a surrogate for myocardial viability in patients with previous infarction and chronic coronary artery disease.⁹⁶

Single Photon Emission Computed Tomography

Thallium. ²⁰¹Tl has been used as a tracer to assess both regional blood flow and myocardial viability.⁸⁴ ²⁰¹Tl is actively transported across the myocyte sarcolemmal membrane via the Na-K⁺ adenosine triphosphatase similar to potassium, and it is extracted from the blood in proportion to myocardial blood flow. Cellular extraction is only diminished when there is irreversible injury to the myocyte, making ²⁰¹Tl an attractive agent for imaging pathophysiologic conditions such as chronic hypoperfusion and posts ischemic dysfunction. Because retention of thallium in the myocardium corresponds to

FIGURE 54-5 ■ A positron emission tomography (PET) viability study. For each panel of four views, perfusion imaging with ^{13}N -labeled ammonia uptake is on the left, and metabolic imaging with [^{18}F]fluorodeoxyglucose (FDG) uptake is on the right. The upper row of each panel is the horizontal long-axis slice with the apex at the top, and the lower row is a vertical long-axis slice with the apex pointing to the left. The yellow and white areas are sites of maximal activity, and the blue areas are sites of minimal activity. The red areas indicate intermediate activity. **A**, Normal images. **B**, An example of ischemia and viable tissue. **C**, An example of myocardial scarring. Note the homogeneous uptake of both ammonia and FDG in the normal study. In the presence of ischemia (**B**), there is a mismatch (arrows), with decreased perfusion and augmented metabolic activity in the apex and the anterior wall. With scarring (**C**), there is equally decreased uptake of FDG and ammonia in the inferior and lateral walls. A, Anterior wall; I, inferior wall; L, lateral wall; S, septum.

cell membrane integrity, regional uptake of thallium corresponds to viable myocardium. As such, decreased myocardial uptake early after ^{201}Tl injection can be due to reduced regional blood flow or infarction. After injection, ^{201}Tl redistributes in the myocardium via continuous exchange between the myocardium and the extracardiac compartments (interstitium, blood pool), driven by the concentration gradient of the tracer and intact myocyte viability. Imaging after redistribution will show less regional heterogeneity of initial ^{201}Tl distribution, thereby reducing the relative difference between the ischemic and normal regions. An increase in regional ^{201}Tl activity on the redistribution images is indicative of myocardium

that has reduced flow but more importantly intact cellular integrity, and thus viability. As such, ^{201}Tl redistribution has been used to distinguish viable from scarred myocardium. ^{201}Tl can be imaged at rest and again 4 hours later to assess redistribution, or by using another injection if part of a stress MPI protocol. Viability can also be assessed quantitatively with ^{201}Tl . The presence of ^{201}Tl uptake greater than 50% to 60% of maximum will be predictive of functional recovery in the majority of segments. Moreover, the final thallium uptake with redistribution appears to be more important than the degree of change from rest to redistribution in predicting recovery.^{97,98}

Technetium-Labeled Tracers. Technetium agents currently are used more commonly than thallium for stress MPI. These agents can still provide insight into the viability of the myocardium. The ability to determine viability from an initial stress-rest MPI study often obviates the need for further testing with PET or thallium protocols. Uptake and retention of the technetium perfusion tracers sestamibi and tetrofosmin require that the myocyte cell and mitochondrial membranes be intact. As such, tracer accumulation indicates cellular integrity, and thus reflects cellular viability.⁹⁹ Computer-assisted quantitative analysis of regional myocardial uptake of sestamibi has been shown to improve accuracy in predicting functional recovery after revascularization, and similar to ²⁰¹Tl, tracer uptake greater than 50% of peak is suggestive of myocardial viability.¹⁰⁰ The administration of nitrates to enhance resting blood and hence tracer uptake has also been studied with ^{99m}Tc-labeled agents because of issues regarding the underestimation of viability with sestamibi compared to PET imaging.^{101,102} Assessment of metabolism for viability with FDG can also be performed using SPECT systems with special equipment (high-energy collimators or coincidence detection).¹⁰³

Prognostic Implications of Viability Assessment

Despite recent advances in medical and antiarrhythmic device therapy for heart failure, patients with ischemic cardiomyopathy and congestive heart failure continue to have a poor prognosis.¹⁰⁴ As mentioned, most patients with chronic ischemic cardiomyopathies have a mixture of scar, hibernation, or stunning. An estimated 20% to 50% of patients with ischemic cardiomyopathies have a significant amount of viable myocardium, thus potentially benefitting from revascularization. Many of these patients would benefit from orthotopic heart transplant, but donor organ supply is limited; therefore, surgical revascularization is often considered to improve survival in these patients. Most observational studies have found that revascularization of hibernating myocardium improves survival and left ventricular function. The selection of appropriate patients for surgical revascularization is largely based on early surgical survival studies that provided insight as to which patients obtain the most benefit from surgical revascularization. The Veterans Administration Cooperative Trial¹⁰⁵ and the Coronary Artery Surgery Study¹⁰⁶ both demonstrated that patients with significant left main or multivessel CAD and depressed ejection fraction (35% to 50%) had better survival with revascularization than medical therapy. Not unexpectedly, these patients often have a high perioperative mortality with coronary artery bypass grafting (CABG).¹⁰⁷⁻¹⁰⁹ In many of these earlier studies, viability was based on the presence of angina. Objective assessment of viability can be useful in these patients to balance the potential benefits of revascularization with the risk of the procedure,¹¹⁰⁻¹¹² especially in those without angina. The potential to improve ventricular function (and moreover survival) with revascularization necessitates an evaluation for hibernating myocardium in most patients with left ventricular dysfunction. However, viability testing

might not be necessary if the patient has angina pectoris or if initial testing revealed stress-induced ischemia.

The clinical endpoints commonly used in viability assessment include recovery of regional or global ventricular function and improvement in symptoms, survival, or both. Most studies focusing on the assessment of myocardial viability have used improvement in ventricular function with revascularization as the clinical endpoint. While useful in comparing the accuracy of the various techniques to determine viability, functional improvement has been used largely as surrogate for outcome, because of the relationship of left ventricular function and outcome. The prognostic implications of PET perfusion-metabolism mismatch and the presence of viability on imaging with thallium or sestamibi has been demonstrated in several studies that have consistently shown similar findings.^{85,112,113} Patients with perfusion-metabolism mismatch have a high mortality when managed medically, and much lower mortality if revascularized. Conversely, those with matched defects, indicating scar, had no such difference in outcomes between medical and surgical management. Although the methods included a combination of techniques and outcomes used (death, nonfatal MI, unstable angina, need for transplant or revascularization) this distinction is not subtle. Patients with demonstrated viability had an annual event rate of 27% if treated medically compared with 6% in similar patients who underwent coronary revascularization.¹¹⁴ On the other hand, patients with matched defects suggesting no viability had similar event rates with medical or surgical treatment. This dichotomy in outcomes underscores the prognostic implication of determining viability. A meta-analysis of pooled data from 24 studies of viability using all currently used techniques encompassing more than 3000 patients further illustrates this point.¹¹² In patients with ischemic cardiomyopathy (mean LVEF, $32 \pm 8\%$), those with demonstrated viability had an annual mortality of 3.2% if treated with revascularization and 16% if treated medically. Those without viability had essentially similar outcomes (7.7% vs. 6.2% mortality, respectively). This analysis provides further evidence that the preoperative determination of viability provides information regarding not only functional recovery, but improvement in survival as well. Results from the recently completed Positron Emission Tomography and Recovery Following Revascularization-2 (PARR-2) showed a trend toward improved 1-year outcome when PET-FDG guided therapy was used compared with standard care.¹¹⁵

Most of the earlier studies performed were not randomized, resulting in an uncertain applicability of optimal medical therapy and inherent selection bias that can confound the results. In 2011, the STICH trial was the first randomized trial to compare surgical revascularization with medical therapy in LV dysfunction^{115a} with the primary outcome of all-cause mortality. At a median follow up of 56 months, medical therapy plus CABG surgery demonstrated no improvement in all-cause mortality; however, demonstrated significantly lower rates of cardiovascular death (28% vs. 33% with medical therapy alone). It is unclear whether the improvement in outcome with revascularization is entirely due to improvement in

LVEF after surgery. Samady and colleagues¹¹⁶ examined survival after CABG in 104 patients with an assessment of function before and after surgical revascularization. Outcome was similar in patients regardless of whether the LVEF improved after CABG, suggesting that revascularization of ischemic myocardium, even without improvement in ventricular function, can prevent future infarction and death. Of note, no formal viability assessment was performed in the majority of these patients. Based on studies such as these, some have advocated revascularization for all patients with ischemic cardiomyopathy asserting that hibernating myocardium should be considered in all patients with CAD and LV dysfunction.¹¹⁶ However, others maintain that preoperative viability assessment provides an opportunity to balance the potential benefit from surgical revascularization against the risks of the procedure.

Dobutamine echocardiography, and more recently cardiac MRI, are alternative modalities to assess myocardial viability. Interestingly, pooled data demonstrate that dobutamine echocardiography has a higher (84% vs. 75%) positive predictive value compared with nuclear and a lower negative predictive value (69% vs. 80%). Cardiac MRI with gadolinium enhancement is a newer modality that is gaining popularity for viability assessment. In cases with severe dysfunction of myocardium (dilated myocardium with thin walls), often conventional techniques (e.g., ²⁰¹Tl) will deem this nonviable territory; however, contrast enhanced CMR may be slightly more sensitive in this scenario.^{116a}

EVALUATION OF PATIENTS AFTER REVASCLARIZATION

Despite technical advances, the effectiveness of both percutaneous and surgical revascularization procedures is limited by restenosis and vein graft closure, respectively.

Progression of the underlying atherosclerosis or development of new stenoses can cause recurrent ischemia, manifesting as recurrence of symptoms, congestive heart failure owing to left ventricular dysfunction, MI, or cardiac death. Symptom status is not a reliable predictor of stenosis after coronary angioplasty, as evidenced by up to 25% of subjects having silent ischemia on treadmill testing.³⁶ However, routine exercise treadmill testing is not currently advocated after coronary angioplasty as it does not reliably detect restenosis.³⁴ SPECT imaging has been demonstrated to accurately detect restenosis, particularly in the 3- to 9-month window of greatest risk for restenosis, with positive and negative predictive values of approximately 90%.⁸⁰ A recent study demonstrated that ²⁰¹Tl stress defect size was predictive of cardiac death and MI, even up to 3 years after percutaneous transluminal coronary angioplasty.⁴⁹ Further study is necessary to evaluate whether routine stress MPI after angioplasty indeed alters prognosis, particularly in asymptomatic patients, and in high-risk subsets of patients (i.e., decreased LV function, multivessel or proximal left anterior descending artery disease, diabetes, renal failure) after angioplasty. The prognostic value of SPECT MPI after CABG

surgery has been studied in more than 2000 patients, consistently demonstrating that the finding of reversible defects on stress SPECT MPI is a strong predictor of worse cardiac outcome in symptomatic subjects early (1 to 5 years) after CABG, and in all subjects more than 5 years after surgical revascularization.

FUTURE DIRECTIONS

While the cornerstone of nuclear cardiology has been myocardial perfusion imaging with SPECT and PET techniques, the field is rapidly expanding in many arenas. Recent technologic advances in hardware and processing have led to the ability to acquire scans in a fraction of the time with conventional cameras. These advances will improve image quality and reduce both imaging time and radiation exposure. The field of cardiac computed tomography (CT) and CT angiography has also led to the development of hybrid cameras, such as PET/CT and SPECT/CT, which will ultimately permit fusion of the anatomic data from CT with the perfusion data from perfusion imaging, which will facilitate the simultaneous assessment of the ischemic burden produced by a given coronary artery stenosis. Novel radiotracers currently under investigation include the fatty acid analogue I-123 BMIPP, which appears to hold promise as a marker of recent myocardial ischemia with "ischemic memory" that can last up to 30 hours after an episode of cardiac chest pain.¹¹⁷ Another new tracer recently approved by the U.S. Food and Drug Administration is iodine-123 metaiodobenzylguanidine, a marker of cardiac adrenergic activity, which can be helpful in determining both response to medical therapy and prognosis in patients with left ventricular dysfunction and heart failure,¹¹⁸ as well as predicting which patients might benefit from an implantable cardiac defibrillator. Both myocardial perfusion imaging and gated blood pool imaging with phase analysis can be used to assess ventricular desynchronization that might be amenable to cardiac resynchronization therapies.¹¹⁹ Other areas currently under investigation include the concept of molecular imaging¹²⁰ of a variety of targets including angiotensin receptors,¹²¹ matrix metalloproteinases,^{122,123} integrins,^{124,125} and other processes involved in angiogenesis.¹²⁶ Advances in PET imaging^{127,128} include flurpiridaz F-18 labeled agents¹²⁹ and the Rb-82 perfusion¹³⁰ tracers. Phase 1 and 2 clinical studies have been completed for F-18, and they have demonstrated higher extraction and shorter positron range thus producing images of higher resolution. These improvements in SPECT technology hold promise to enhance the ability to image novel processes, as well as reducing both imaging time and radiation exposure.¹³¹ Such new approaches will undoubtedly contribute to the clinical utility of nuclear cardiology imaging techniques in the evaluation and management of patients with known or suspected heart disease.

CONGENITAL HEART DISEASE

Echocardiography has broad utility in the diagnosis and management of cardiovascular disease. Echocardiography allows for real-time, precise anatomic definition and physiologic interrogation of cardiac and vascular structures at relatively low cost with minimal patient risk and discomfort. Common clinical applications for echocardiography include assessment of myocardial and valvular function, identification of structural abnormalities, and optimizing timing for surgical intervention.¹⁻⁴ Echocardiography has expanded beyond the diagnostic laboratory to include the intensive care unit, emergency department, operating room, and electrophysiology and cardiac catheterization laboratories.⁵ This chapter will briefly review the basic principles of ultrasound imaging, echocardiographic approaches, and clinical applications of echocardiography (Table 55-1).^{4,6}

BASIC PRINCIPLES

Echocardiographic images are generated from analyses of reflected ultrasound waves from piezoelectric crystals. Ultrasound waves are beyond audible sound wave range

(>20 kHz). Ultrasound waves reflect off internal structures, such as the heart and vasculature, and they are reflected back to the transducer. Analysis of the intensity and timing of these reflected sound waves allow for image generation. Propagation of ultrasound waves is optimal through liquid medium (blood). In contrast, air and bone cause significant acoustic impedance, resulting in poor ultrasound penetration. Therefore, suboptimal image generation occurs with intervening structures such as ribs or surface bandages, or if images are acquired through air-filled lungs or subcutaneous air. Factors that affect ultrasound propagation will affect image quality, such as ultrasound beam refraction, beam attenuation due to absorption of ultrasound energy by tissue, and disarrayed beam reflection or scatter.^{2,3}

ULTRASOUND IMAGING MODALITIES

Echocardiographic examinations include the use of several ultrasound modalities, including M-mode, two-dimensional imaging, color flow imaging, and spectral Doppler imaging, with continuous-wave and pulsed

TABLE 55-1 Indications for Echocardiography

Diagnosis	Key Echocardiographic Findings	Limitations of Echocardiography
Cardiomyopathy		
	LV size, wall thickness, and systolic function RV size and function PA pressure estimate Valvular anatomy and dysfunction	
Valvular Heart Disease		
Valve stenosis	Etiology and severity of stenosis LV and RV size and systolic function PA pressure estimate	May underestimate stenosis severity
Valve regurgitation	Mechanism and etiology of regurgitation Severity of regurgitation PA pressure estimate	TEE and 3D imaging may be needed to evaluate MR and valve anatomy
Prosthetic valves	Evidence for stenosis or regurgitation PA pressure estimate	Imaging prosthetic valves limited by artifact TEE needed for suspected prosthetic MR
Endocarditis	Detection of vegetations, abscess Presence, degree of valve dysfunction	TEE increases sensitivity for detecting vegetations and abscess
Coronary Artery Disease		
Acute MI	Segmental wall motion abnormality reflects “myocardium at risk” Global LV function (EF) Evaluate for MI complications	Coronary artery anatomy not directly visualized
Angina	Global and segmental LV function Exclude other causes of angina (e.g., AS, HOCM)	Resting wall motion may be normal despite significant CAD Stress echocardiography needed to induce ischemia
End-stage ischemic disease	Global and segmental LV function RV function, PA pressures	
Pericardial Disease		
	Pericardial thickening Detection, size, location of pericardial fluid Signs of tamponade physiology	Tamponade is a hemodynamic and clinical diagnosis (blood pressure, heart rate)
Aortic Disease		
Aortic root dilation	Etiology of aortic dilation Accurate aortic diameter measurements Associated aortic regurgitation	
Aortic dissection	Accurate aortic diameter measurements Imaging of dissection “flap” (dissection) Associated aortic regurgitation	TEE more sensitive and specific Cannot assess distal vascular beds
Cardiac Masses		
LV/LA thrombus	TTE has high sensitivity and specificity for LV thrombus	TEE is needed to detect LA thrombus reliably
Cardiac tumors	Size, location, and physiologic consequences of tumor mass	Extracardiac involvement not well seen Cannot distinguish benign from malignant, or tumor from thrombus
Pulmonary HTN		
	RV size and systolic function PA pressure estimate	
Congenital Heart Disease		
	Detection of anatomic abnormalities Quantitation of physiologic abnormalities LV and RV size and systolic function	No direct intracardiac pressure measurements Saline contrast may be needed to assess intracardiac shunts

3D, Three-dimensional; AS, aortic stenosis; CAD, coronary artery disease; EF, ejection fraction; HOCM, hypertrophic obstructive cardiomyopathy; HTN, hypertension; LA, left atrial; LV, left ventricular; MI, myocardial infarction; MR, mitral regurgitation; MV, mitral valve; PA, pulmonary artery; RV, right ventricular; TEE, transesophageal echocardiography; TR, tricuspid regurgitation; TTE, transthoracic echocardiography.

Adapted from Otto CM, Schwaegler RG, Freeman RV: *Echocardiography review guide*, ed 2, Philadelphia, 2011, WB Saunders, pp 89–91.

Doppler ultrasound. Because images are generated from reflected signals, they are not truly “real-time,” but image processing is rapid, making the time differential indiscernible. Two-dimensional (2D) echocardiography displays images using a simultaneous ultrasound array across a tomographic plane at a frame rate of 50 to 60 frames/

second. Transthoracic echocardiography uses transducer positions that provide acoustic access to the heart: parasternal, apical, subcostal, and suprasternal (Fig. 55-1). From these “windows,” tomographic image planes are aligned with respect to the cardiac anatomy in long-axis, short-axis, and apical four-chamber and two-chamber

FIGURE 55-1 ■ Standard acoustic windows for transthoracic echocardiography. Parasternal and apical windows are obtained with the patient in a left lateral position. The subcostal window is obtained with the patient supine and legs flexed, to relax the abdominal wall. The suprasternal notch window is obtained with the patient's head tilted to the side to aid transducer placement. (From Otto CM, Schwaegler RG, Freeman RV: *Echocardiography review guide*, Philadelphia, 2011, WB Saunders, Figure 2-6.)

FIGURE 55-2 ■ **A**, Parasternal long axis view in a patient with dilated cardiomyopathy shows the anteroseptum and posterior wall of the left ventricle. **B**, Parasternal short axis view in a patient shows a cross-section through the mid-portion of ventricles. **C**, Apical four-chamber view shows the lateral (Lat. wall) and inferoseptal walls of the left ventricle (LV) and the free wall of the right ventricle. **D**, Apical two-chamber view shows anterior (Ant. wall) and inferior walls of the LV.

views (Fig. 55-2).⁷ Acoustic shadowing from structures that block ultrasound wave propagation, such as prosthetic valves or calcification, will block imaging distal to the structure. For example, a mechanical mitral prosthesis imaged from a transthoracic window creates acoustic shadowing of the left atrium and an inability to evaluate regurgitation severity (Fig. 55-3). Although most diagnostic echocardiography requires full ultrasound systems, smaller, handheld devices are increasingly available for portable, bedside diagnostic testing in intensive care units, emergency departments, and similar clinical settings. Recognition of ultrasound image artifacts is essential to identify abnormal findings correctly. Common

FIGURE 55-3 ■ Apical four-chamber view in a patient with a mechanical mitral valve. Acoustic shadowing distal to the valve obscures visualization of the left atrium (LA). LV, Left ventricle.

FIGURE 55-4 ■ M-mode tracing from a patient with aortic regurgitation and a dilated left ventricle (LV). LV wall thickness and chamber size are shown throughout the cardiac cycle. Diastolic measurements of the septum (S), LV chamber size, and posterior wall (PW) are shown.

artifacts include reverberations, beam width artifacts, and beam refraction, as well as external artifacts from electronic effects on the ultrasound machine, such as electrocautery during imaging.

M-mode (motion) echocardiography is produced by displaying reflected signals received from an ultrasound beam against the time dimension (Fig. 55-4). Because data from a single ultrasound beam are used, temporal (timing) resolution for M-mode is excellent, with an imaging frame rate greater than 1800 frames per second.

M-mode is useful for measurement of cardiac dimensions, for timing of events such as valve opening and closing, and for demonstrating rapid, fine motion such as fluttering of the anterior mitral valve leaflet with aortic regurgitation or independent mobility of valvular vegetations.

Transesophageal echocardiography (TEE) is a semi-invasive procedure in which the transducer is mounted on a flexible endoscope and positioned in the esophagus and stomach. Manipulation of the TEE probe is constrained by esophageal anatomy, and oblique image planes can hinder acquisition of standard images.⁸ However, image resolution for TEE is significantly improved over transthoracic echocardiography (TTE) because of the lack of intervening air or bone. Transesophageal imaging allows for better visualization of posterior cardiac structures, such as the mitral valve, left atrium, left atrial appendage, interatrial septum, and thoracic aorta. TEE is more accurate than TTE for identifying valvular vegetations and complications of endocarditis, aortic pathology, and mitral valve abnormalities. TEE is used to identify left atrial thrombus as a potential cardiac source of distal embolic disease and to exclude thrombus presence before direct current cardioversion for atrial fibrillation (Fig. 55-5).⁹ In the intensive care unit, TEE has been used in determining the etiology of unexplained hypotension,¹⁰ and it is helpful in evaluating patients after cardiac surgery at increased risk for ischemia, hypovolemia, and pericardial tamponade.¹¹ However, TEE usually requires conscious sedation to reduce patient discomfort, with additional monitoring and nursing support.

Three-dimensional (3D) echocardiographic images display cardiac anatomy using a simultaneous ultrasound array across a pyramidal volume.¹² Image processing from the large data set decreases the imaging frame rate even lower than 2D imaging, but spatial resolution is further

improved. Both transthoracic and transesophageal 3D imaging transducers are available. Image processing of 3D volume data sets can systematically “cut away” portions of the volume to provide two-dimensional image planes analogous to standard long-axis, short-axis, and four-chamber views. Intraprocedural 3D TEE imaging is increasingly being used to aid operators, such as in aortic annulus cross-sectional area sizing for transcatheter aortic valve placement, percutaneous closure device placement, and procedural success of mitral balloon valvuloplasty (Fig. 55-6).^{13,14}

Contrast echocardiography is performed in conjunction with echocardiography to opacify cardiac chambers. Contrast agents include intravenous agitated saline to opacify the right heart chambers for detection of intracardiac shunts (Fig. 55-7), and commercially made microbubble agents that traverse the pulmonary bed to provide left heart opacification. Opacification of the left-sided cardiac chambers enhances endocardial border definition to aid in wall motion analysis when image quality is suboptimal (Fig. 55-8).¹⁵ Although microbubble transpulmonary contrast can provide information on myocardial perfusion, this methodology is still in development.^{16,17}

Epicardial intraoperative echocardiography is performed by placing the transducer directly on the heart during cardiac surgery. This modality is used when anterior structures are suboptimally seen with a transesophageal approach. In intravascular ultrasound, imaging is performed via a percutaneously placed intravascular catheter. The most common use of this technique is intracoronary transducer placement to assist in plaque characterization and assessment of stenosis severity and intracardiac transducers used in the catheterization and electrophysiology laboratories for periprocedural aid in catheter placement.

FIGURE 55-5 ■ Imaged using transesophageal echocardiography, an atrial thrombus is seen in the left atrial appendage (arrow) in a patient with atrial fibrillation undergoing evaluation for elective cardioversion. Low-velocity blood flow is evidenced by the spontaneous echo contrast seen at the ostia of the left atrial appendage.

FIGURE 55-6 ■ Three-dimensional transesophageal echocardiography during a mitral valvuloplasty procedure imaged from the atrial side of the valve with a catheter crossing the valve and the valvuloplasty balloon inflated. MV, Mitral valve.

DOPPLER ECHOCARDIOGRAPHY

Doppler echocardiography provides information on the direction and velocity of blood flow.^{1,3} Reflected frequencies from an object moving toward a sound source are higher than the original signal, and are lower from an object moving away from the sound source. Doppler echocardiography measures Doppler shift in the reflected signals from moving red blood cells. By convention, frequency shifts toward the transducer are shown above the

FIGURE 55-7 ■ Opacification of the right atrium (RA) and right ventricle (RV) with intravenous agitated saline contrast. The presence of an interatrial shunt is demonstrated by right-to-left shunting across the septum with bubbles (*arrow*) in the left atrium and left ventricle (LV) within three cardiac cycles.

zero baseline, and shifts away from the transducer are shown below the baseline. Importantly, detecting maximum velocity relies on parallel alignment of the ultrasound beam with the direction of blood flow, and a nonparallel intercept angle will result in erroneous data with underestimation of maximum velocity.

With pulsed wave Doppler (PWD), the transducer alternates between sending and receiving signals, sampling blood velocities at a specified depth along the ultrasound beam. There is a limited measurable maximal velocity with PWD (the “Nyquist limit”) beyond which the signal aliases and peak velocity cannot be accurately measured. With continuous wave Doppler (CWD), the transducer continuously transmits and receives signals along the entire length of the ultrasound beam. Although the specific depth origin of the CWD velocity cannot be localized, signal aliasing does not occur, and higher blood velocities, such as seen in stenotic valves, can be measured.

PWD and continuous wave Doppler (CWD) velocity data are displayed as a graph of velocity versus time, with signal strength displayed using a decibel grey scale. By convention, frequency shifts toward the transducer are shown above the baseline. The velocity time integral (VTI) is the integral of blood flow velocity over time, measured in distance. The shape, timing, and density of spectral Doppler images provide valuable qualitative evaluation of blood flow, and increased jet density suggests increased flow volume. Rapid equalization of pressure gradients between two cardiac chambers leads to steeper jet slopes (Fig. 55-9). Color Doppler echocardiography is an application of pulsed Doppler imaging in which data from multiple PWD samples across a 2D imaging sector are combined and velocities are mapped onto a color scale. These color maps are then superimposed onto a 2D image, providing directional blood flow information. By convention, flow toward the transducer is displayed in red and flow away is displayed in blue, with the color transition occurring at the Nyquist limit. Color Doppler echocardiography is used for qualitative

FIGURE 55-8 ■ Abnormal stress echocardiogram with images of the apical four-chamber view taken at rest (**A**) and following administration of dobutamine (**B**). Transpulmonary microbubble contrast is used to opacify the left ventricular chamber. After dobutamine administration, there is a wall motion abnormality, with hypokinesia and contour change in the apex and distal septum of the left ventricle (*dots*).

evaluation of valve regurgitation by examining the timing and extent of flow disturbance created by the regurgitant jet. Severity is usually rated on a scale of 1+ (mild) to 4+ (severe).

Doppler echocardiography is invaluable for evaluation of valve regurgitation.^{18,19} Color Doppler mapping aids in visualization of the jet origin and direction. Measurement of the narrowest jet width on color Doppler imaging (vena contracta) at or just distal to the regurgitant orifice is a simple measure that correlates with regurgitation severity (Fig. 55-10). Accuracy in measuring the vena contracta is crucial because small errors lead to inaccurate assessment of regurgitation severity. Other qualitative

FIGURE 55-9 ■ Spectral Doppler tracing of a patient with severe aortic regurgitation. The Doppler density of regurgitant flow (above the baseline) is nearly equal to anterograde flow (below the baseline). There is a steep aortic regurgitant Doppler slope, suggesting rapid equalization of pressures between the aorta and left ventricle. AR, Aortic regurgitation; Decel, time duration for velocity deceleration; P ½, time duration for pressure gradient to decrease by half.

markers of regurgitation severity include flow reversal of the Doppler signal in adjacent upstream vascular structures, seen when regurgitation severity is moderate or greater.

When combined with qualitative measures, Doppler echocardiography allows for hemodynamic assessment, such as quantitation of valve stenosis and regurgitation severity, cardiac stroke volume, ventricular systolic and diastolic function, and intracardiac pressure calculation. There are three primary Doppler principles used in clinical practice: (1) flow quantitation (stroke volume calculation), (2) continuity of flow, and (3) pressure/velocity (Bernoulli's equation). The stroke volume (SV) traversing a cardiac orifice is the product of the cross-sectional area (CSA) at that point and the velocity time integral (VTI_{FLOW}).

$$SV = CSA \times VTI_{FLOW}$$

Cross-sectional area, assuming a circular orifice, is calculated by measuring the diameter at the point of interest ($Area = \pi r^2$). The velocity time integral is obtained from spectral Doppler interrogation. The principle of continuity of flow describes the concept that the stroke volume passing just proximal to an orifice (SV_{pre}) is the same as the stroke volume passing through the orifice ($SV_{orifice}$). The most common application of the continuity equation is in aortic valve area measurement for stenosis where the stroke volume (SV_{pre}) is measured at the left ventricular outflow tract, discussed in further detail in the valve stenosis portion of this chapter. The principle of continuity of flow is also used for the calculation of regurgitant orifice size and volumes using the flow convergence proximal to the regurgitant valve proximal isovelocity surface area [PISA]). The PISA method uses the principle that blood accelerates in a laminar fashion toward a regurgitant orifice, forming multiple “hemispheres” of isovelocity (Fig. 55-11). Effective regurgitant orifice size (EROA) can then be calculated from flow velocities.²⁰

When a blood flow stream narrows, (i.e., when traversing a valve orifice), flow velocity (v) increases in proportion to the degree of narrowing. Increases in velocity are correlated with increased pressure gradients across

FIGURE 55-10 ■ Vena contracta, the narrowest portion of the jet just distal to the regurgitant orifice for aortic valve (A) and mitral valve (B) regurgitation. Ao, Aorta; LA, left atrium; LV, left ventricle.

FIGURE 55-11 ■ Regurgitation severity quantification by proximal isovelocity surface area (PISA) method. As blood flow approaches a regurgitant orifice, velocity increases, forming concentric isovelocity hemispheres. Measurement of the aliasing blood velocity, measured at the hemisphere margin, and the radius provide data on the regurgitant instantaneous flow rate and the effective regurgitant orifice area.

FIGURE 55-12 ■ Severe aortic stenosis (AS), with thickened, calcified aortic valve leaflets on the parasternal long axis view. On continuous Doppler imaging across the aortic valve, the peak velocity (V) is 4.5 m/s, corresponding to a peak gradient (PG) of 80 mm Hg, using the simplified Bernoulli equation. Ao, Aorta; LA, left atrium; LV, left ventricle.

the orifice, and this is described by the Bernoulli equation (pressure–velocity relationship). Ignoring the effects of viscous loss and local red blood cell acceleration, the relationship is simplified to:

$$\text{Pressure gradient} = 4v^2$$

Estimation of transvalvular pressure gradients is a common application of the Bernoulli equation (Fig. 55-12). Another common application is the estimation of pulmonary arterial pressures. The pressure gradient between the right ventricle and right atrium is calculated using the systolic velocity from the tricuspid regurgitant jet (Fig. 55-13). In the absence of pulmonary stenosis, pulmonary arterial systolic pressure is equal to the sum of

FIGURE 55-13 ■ Peak pressure gradient is calculated using peak velocity (V) from the continuous Doppler tracings of the tricuspid regurgitant jet using the simplified Bernoulli equation. Peak velocity of 2.5 m/s corresponds to a peak pressure gradient (right ventricular systolic pressure) of 25 mm Hg. Pulmonary arterial systolic pressure is obtained by adding estimated right atrial pressure to the peak gradient.

FIGURE 55-14 ■ Inferior vena cava (IVC) diameter at rest in a patient with mildly increased right atrial pressures. RA, Right atrium.

right ventricular (RV) systolic pressure and right atrial pressure. Right atrial pressure is obtained by examining inferior vena cava (IVC) diameter at rest and with inspiration, measured before the junction to the right atrium (Fig. 55-14 and Table 55-2).²¹ Measurement of pulmonary arterial systolic pressure is widely applicable as 90% of individuals have some degree of tricuspid regurgitation.

VENTRICULAR FUNCTION

Systolic Function

Echocardiographic imaging allows for rapid, accurate, and reproducible assessment of global and regional left

TABLE 55-2 **Right Atrial Pressure Estimation**

Inferior Vena Cava Diameter	Change in Diameter with Inspiration	Right Atrial Pressure Estimation
Normal ≤ 2.1 cm	Decrease in diameter > 50%	3 mm Hg
Normal ≤ 2.1 cm	Decrease in diameter ≤ 50%	8 mm Hg
Dilated ≥ 2.5 cm	Decrease in diameter ≤ 50%	15 mm Hg

From Rudski LG, Lai WW, Afalalo J, et al: Guidelines for the echocardiographic assessment of the right heart in adults. *J Am Soc Echocardiogr* 23:685–713, 2010.

FIGURE 55-15 ■ Endocardial border tracings of the left ventricle (LV) from the apical four-chamber view during diastole and systole are used to calculate LV volumes. Using concordant LV volume calculations from the apical two-chamber view, ejection fraction is calculated using the apical biplane method of disks algorithm. *Volume, MOD, Calculated LV volume.*

ventricular (LV) systolic function. Left ventricular ejection fraction (EF), estimates global systolic function by using end-diastolic volume (EDV) and end-systolic volume (ESV).⁷ Volumes are typically calculated using geometric formulas based on endocardial border tracings from two orthogonal views of the LV (Fig. 55-15).

$$EF = 100\% \times (EDV - ESV) / EDV$$

The most commonly applied algorithm is the biplane apical summation of discs method. Because the LV is assumed to be symmetric and bullet shaped to make this calculation, standard, nonoblique imaging planes are needed for optimal measurement. Rather than using geometric assumptions to estimate LV volumes, direct measurement of LV volumes is now possible with 3D imaging. With visualization of variability in the LV endocardial contour, 3D-derived LV volumes tend to be larger than 2D volumes (Fig. 55-16). However, EF measurement accuracy relies on optimal endocardial definition, and image quality for 3D datasets remains relatively limited compared with 2D images. Therefore, 2D EF measurements remain the mainstay of LV systolic function assessment. A novel index of LV function, global longitudinal strain, uses computer algorithms which track natural acoustic markers in the myocardium (Fig. 55-17). Global strain imaging is primarily used in research applications and is not yet commonly applied in standard imaging.

Echocardiographic assessment of systolic function is more challenging with segmental wall motion abnormalities and with arrhythmia, in which variability in cardiac

cycle length affects beat-to-beat left ventricular volumes. Patients with conduction delay or who have previously undergone cardiac surgery may have dyssynchronous activation of the interventricular septum. When image quality precludes endocardial border tracing, qualitative assessment by an experienced echocardiographer is a reasonable alternative. Visual estimates of EF are usually reported in increment ranges of 5% or 10% (e.g., 50%-55% or 20%-30%).

A Doppler-derived measure of LV systolic function uses the early systolic rate of velocity increase in the mitral regurgitant jet, a relatively load-independent measure of contractility (Fig. 55-18). The slope of the mitral regurgitant jet between two points on the velocity curve represents the rate of change in LV pressure over time (dP/dt). A normal dP/dt is greater than 1000 mm Hg/sec; a lower dP/dt slope is concordant with a delay in LV systolic pressure generation and depressed LV function.

Right ventricular function is usually reported qualitatively on a scale of normal, mildly, moderately, or severely depressed. Multiple views of the right ventricle are often needed to provide a reasonable assessment of global systolic function. Semiquantitative measures of RV function are difficult because, as opposed to the LV, geometric assumptions of symmetry are not valid. The RV free wall “wraps” around the left ventricle, forming a crescent shaped chamber. The most commonly used measure is the tricuspid annular plane systolic excursion, a single-plane M-mode distance measurement for which greater than 1.8 cm suggests normal systolic function (Fig. 55-19).

FIGURE 55-16 ■ Three-dimensional volume data set of the left ventricle (LV) with an end-diastolic volume (EDV) of 64.9 mL, an end-systolic volume (ESV) of 29.8 mL, a stroke volume (SV) of 35.1 mL, and an LV ejection fraction of 54.1%.

FIGURE 55-17 ■ Strain imaging from the apical four-chamber view. Strain measurement from each segment is color coded and displayed on the graph below the imaging against time. A composite “global” longitudinal strain measurement is provided in the lower left hand portion of the image (G.L. strain = -25%). Normal longitudinal strain measurement is less than -20. All segmental and global strain measurements are normal in this patient.

FIGURE 55-18 ■ Continuous wave Doppler tracings of the mitral regurgitant jet showing a decreased rate of rise to the peak LV cavity pressure during early systole in a patient with severely reduced LV systolic function and ejection fraction of 25% (dP/dt). With normal systolic function, the change in rate of rise in pressure over time should be greater than 1000 mm Hg/sec. Δt , Change in time; V_{max} 1, first velocity measured; V_{max} 2, second velocity measured.

FIGURE 55-19 ■ M-mode tracing of the tricuspid annular motion against the time dimension. Vertical distance between the lowest point and greatest systolic motion is measured. This patient has a distance measurement of 3.1 cm (greater than 1.8 cm suggests normal systolic function). ΔT , Change in time.

Diastolic Function

Diastole comprises four phases: (1) isovolumic relaxation, (2) atrioventricular valve opening with passive early rapid ventricular filling, (3) diastasis, or deceleration of passive LV filling owing to equalization of atrial and ventricular pressures, and (4) late active ventricular filling owing to atrial contraction. Several echocardiographic parameters are used to evaluate diastolic function.^{22,23} Increased left atrial size is a surrogate measure of increased left atrial

FIGURE 55-20 ■ Doppler indices for mild diastolic function. With impaired ventricular relaxation, peak early mitral inflow velocity is decreased. Increased reliance on atrial contribution to ventricular filling leads to reversal of the E:A ratio on the left ventricular (LV) inflow tracing. A ratio of LV inflow E wave to tissue Doppler velocity (TDI) E' wave (E:E' ratio) less than 8 implies normal left atrial pressure. In this case, E:E' = 0.6/0.1 = 6.

(and LV end-diastolic) pressures. Pulse wave Doppler indices include the evaluation of LV inflow velocities with early “E” wave filling and the atrial contribution to filling (“A” wave). The “E” wave deceleration time (DT) and isovolumic relaxation time (IVRT) are measures of LV relaxation.

In normal, young individuals, early filling is the dominant component of LV filling with atrial contraction contributing less than 20% to total filling volume. Therefore, the E wave is higher with an E:A ratio greater than 1. With aging, ventricular stiffness increases, there is delay or impaired myocardial relaxation, and the relative contribution of atrial contraction is increased, with reversal of the E and A velocities and E:A ratio less than 1 (Fig. 55-20). In advanced diastolic dysfunction, decreased LV compliance leads to rapid equalization of the transmitral diastolic pressure gradient. With increased LV end-diastolic pressure, atrial contribution to LV filling is small, manifesting as an E:A ratio greater than 2, a steep deceleration slope and shortened IVRT (Fig. 55-21). Although patients in transition from an impaired relaxation pattern to a restrictive pattern have decreased LV compliance, the E:A ratio may appear normal, making interpretation of diastolic indices difficult.

FIGURE 55-21 ■ With advanced diastolic dysfunction (restrictive filling), there is decreased left ventricle (LV) compliance. High left atrial pressures drive transmitral filling with a higher, early peaked E wave and E:A ratio greater than 2. A ratio of LV inflow E wave to tissue Doppler velocity (TDI) E' wave (E:E' ratio) greater than 15 implies elevated left atrial pressure. In this case, $E:E' = 1.7/0.07 = 24$.

Loading conditions (heart rate, volume overload, mitral regurgitation) affect left atrial pressure and transmitral gradients. Mitral inflow evaluation repeated during a Valsalva maneuver (transient preload decrease) can unmask diastolic dysfunction, aiding in diagnosis.

Tissue Doppler interrogation at the septum and lateral wall just below the mitral annulus allows evaluation of myocardial diastolic motion. Myocardial early (E') and atrial (A') waves correspond to mitral E and A waves and are less sensitive to atrial loading than mitral inflow (see Figs. 55-20 and 55-21). The transmitral E to myocardial E' (E:E') ratio is a strong surrogate measure of LV filling pressure, with a ratio less than 8 suggesting normal left atrial pressure and a ratio greater than 15 increased left atrial pressure. A ratio between 8 and 15 is indeterminate.

Abnormalities in diastolic indices can also be seen with extracardiac constraint of ventricular filling such as in constrictive pericarditis or tamponade. Normal RV filling demonstrates mild respiratory variation in transtricuspid velocities. On inspiration, there is an increase in systemic venous return and a transient increase in velocities, with normal magnitude increase less than 20%. Because left atrial filling is not respiratory dependent, transmitral velocities do not normally vary significantly with

FIGURE 55-22 ■ Pericardial effusion (PE) in a patient with dyspnea. The transmitral pulsed Doppler tracing demonstrates respiratory variation in flow. Ex, Expiration; Insp, inspiration.

respiration. With pericardial tamponade and chronic pulmonary disease, exaggerated inspiratory-expiratory respiratory variation in the transtricuspid and transmitral velocities may be seen (Fig. 55-22).

ISCHEMIC HEART DISEASE

Direct visualization of coronary artery anatomy by echocardiography is rarely possible beyond visualization of coronary ostia. However, echocardiography is well suited to visualize effects of altered coronary perfusion on endocardial motion and wall thickening. With impaired coronary blood flow, segmental wall motion abnormalities are seen in affected myocardium. Myocardial responses to ischemia include hypokinesis (myocardial thickening with relatively less inward motion than the rest of the myocardium), akinesis (absence of thickening or inward motion), and dyskinesis (thinned and infarcted myocardium with paradoxical outward systolic motion).

Myocardial response to ischemia is to the severity of ischemia, hypokinesis progressing to akinesis in more severe cases. Although acutely infarcted myocardium appears hypokinetic, wall thickness may be normal as postinfarct remodeling has not yet occurred. In patients with an acute, ST elevation infarction, myocardial segments subject to prolonged ischemia are likely to remain hypocontractile in the long term, whereas segments subjected to only a short duration of coronary flow limitation may return to a normal contractile state. Postinfarction myocardial dysfunction that subsequently returns to normal is termed *stunned myocardium*. Irreversibly infarcted regions appear thinned and akinetic with persistent akinetic or dyskinetic wall motion on long-term evaluation.

Echocardiography is useful in the detection of coronary disease in patients with chest pain symptoms. In patients with active chest discomfort, the absence of regional wall motion abnormalities on a resting study is an effective means of ruling out acute ischemia (negative

predictive accuracy of $\approx 95\%$). In the operating room, intraoperative TEE allows for continuous monitoring of cardiac function and has been used during coronary revascularization and to monitor patients undergoing noncardiac surgery at high risk of cardiac events. TEE has also proven useful to evaluate cardiac function in the hemodynamically unstable patients in whom ischemia is suspected, but in whom transthoracic windows are suboptimal.

Takotsubo cardiomyopathy, or “stress cardiomyopathy,” is acute, cardiac syndrome characterized by chest pain or dyspnea following a significant emotional or physiologic stress. The echocardiographic manifestation is transient akinesis of the apical and mid-LV segments with regional wall motion abnormalities that extend beyond a single epicardial coronary arterial distribution. Angiography demonstrates the absence of obstructive coronary disease or acute plaque rupture. Outcome is generally good, and ventricular functional recovery is likely with supportive care.^{24,25}

Stress Testing for Coronary Disease

Stress echocardiography is useful for initial diagnosis of coronary disease, monitoring disease progression in patients with known coronary lesions, and evaluating the functional significance of residual lesions following revascularization. Stress echocardiography provides visualization of myocardial function during active stress, allowing for diagnosis of myocardial ischemia in a controlled setting.^{26,27} Accuracy for stress echocardiography to determine extent and location of myocardial ischemia is excellent, and it is particularly useful when baseline electrocardiograph (ECG) abnormalities render standard exercise ECG testing nondiagnostic. The addition of imaging increases sensitivity and specificity over standard exercise ECG stress testing. Various exercise (treadmill or bicycle ergometer) and nonexercise cardiac stressors (dobutamine) are used. Echocardiographic images are acquired at rest and at peak stress. For treadmill protocols, images are acquired immediately after cessation of exercise because of imaging difficulties while the patient is upright on the treadmill. Images are integrated with ECG data, exercise tolerance, and patient symptoms for final interpretation. Using standard views of the LV, side-by-side comparison of the rest and stress digital images allow identification of wall motion abnormalities (see Fig. 55-8). Ischemia diagnosis is dependent on accurate evaluation of segmental wall motion and interval change from rest images. As a consequence, diagnosis of ischemia is more difficult in patients with preexisting coronary artery disease and resting segmental abnormalities. When endocardial definition is suboptimal, intravenous contrast agents can be used to opacify the LV cavity and aid in endocardial border definition. Results of stress echocardiography testing offer long-term prognostic information.²⁸⁻³⁰

In the absence of significant coronary narrowing, the myocardial response to stress is augmentation of systolic function with hyperdynamic motion. Flow-limiting coronary lesions are associated with systolic dysfunction in the myocardial region distal to the lesion. In noninfarcted

myocardium, systolic function is preserved if coronary blood flow is adequate to meet oxygen demand at rest. The ischemic effect on ventricular wall motion and thickening is proportional to the severity of impaired coronary blood flow. For intermediate range lesions (50%-60% stenosed) or single-vessel disease in which only a few myocardial segments are affected, ischemic abnormalities may be subtle or transient. With cessation of the stressor and restoration of adequate coronary flow, wall motion returns to normal. A submaximal stress test lowers test sensitivity because provocation of ischemia is dependent on reaching an adequate workload. Prolonged delay in obtaining stress images also lowers sensitivity because ischemia detection requires the abnormality to persist long enough for image recording.

Exercise stress echocardiography is performed following a standard symptom limited protocol to achieve as high a workload as possible. When testing cannot be performed because of physical limitation or when exercise response may be limited, pharmacologic stressors such as dobutamine are alternatives to exercise. Dobutamine is typically initiated at 10 mg/kg/min and is increased at 3-minute intervals to a maximum of 40 mg/kg/min. If target heart rate (85% of the patient's maximum predicted heart rate) is not achieved, atropine can be additionally administered. Dobutamine stress testing is commonly used to monitor for transplant vasculopathy in post-cardiac transplant patients, in whom denervated hearts might not allow the achievement of target heart rate with exercise protocols.

Complications of Acute Myocardial Infarction

Echocardiography is the diagnostic tool of choice to evaluate for complications of myocardial infarction. Two-dimensional imaging allows assessment of myocardial function and regional wall motion abnormalities. Mitral regurgitation is a common complication of ischemic disease. In patients with regional wall motion abnormalities and LV chamber enlargement, significant mitral regurgitation can result from distortion of the mitral subvalvular apparatus. Mitral regurgitation can also occur as a direct result of papillary muscle ischemia, rupture of a necrotic papillary muscle head, and infarct scarring with tethering of the subvalvular apparatus.

Myocardial necrosis with ventricular rupture can be identified in the free wall and the interventricular septum. A ventricular septal defect is identified by characteristic color flow and continuous-wave Doppler flow across the defect. A ventricular pseudoaneurysm, a contained ventricular free wall rupture, often has an abrupt transition from normal myocardial tissue to the aneurysmal dilation and thrombus within the cavity (Fig. 55-23). Myocardial infarction with ventricular wall thinning can also lead to focal dilation and true aneurysm formation. As with pseudoaneurysms, thrombi can form within ventricular aneurysms and pose a risk of distal embolization.

Mural thrombi occur primarily in anterior and apical infarctions, and they are less frequent with early revascularization (Fig. 55-24). A cause of hypoxemia following inferior myocardial infarction is increased right-sided

FIGURE 55-23 ■ Pseudoaneurysm in a patient with a prior ST elevation inferior myocardial infarction. The inferior wall of the left ventricle (LV) appears thinned and bright. There is a rupture of the base of the heart with a large pseudoaneurysm adjacent to the LV. Within the pseudoaneurysm, there is a large spherical thrombus. LA, Left atrium.

FIGURE 55-24 ■ Small apical thrombus (arrow) in the left ventricle (LV) in a patient with a recent anteroapical myocardial infarction. RV, Right ventricle.

pressures with resulting right-to-left shunting across a patent foramen ovale. This hypoxemia can be diagnosed by TEE evaluation of the intra-atrial septum with a contrast study using agitated saline contrast. A similar phenomenon has been described in postoperative hypoxemic patients with increased right atrial pressure.³¹

CARDIAC MASSES

Image resolution with echocardiography is excellent, with cardiac masses as small as 1 to 2 mm in diameter being visualized. It is important to correlate any findings of a potential cardiac mass with the clinical history to

FIGURE 55-25 ■ Right ventricular pacer lead (arrow) seen crossing the tricuspid valve into the right ventricle (RV). RA, Right atrium.

FIGURE 55-26 ■ Atrial septal defect closure device that was placed percutaneously. Prosthetic material appears bright and echogenic, spanning the interatrial septum (arrows). LA, Left atrium; LV, left ventricle; RA, right atrium; RV, right ventricle.

identify expected structures such as pacing wires, central venous catheters, prosthetic valves, and intra-cardiac devices (Figs. 55-25, 55-26, and 55-27). In addition, potential masses seen on echocardiography should be scrutinized carefully to exclude ultrasound artifact and normal structural variants. Commonly encountered cardiac masses include normal structures, tumors, thrombi, and vegetations. These categories are not mutually exclusive (i.e., a vegetation often also includes adherent thrombi).

Findings suggesting low-velocity blood flow, such as myocardial hypofunction and spontaneous echo contrast, are associated with relative blood stasis and thrombus formation. In the LV, these findings are usually at the sites

FIGURE 55-27 ■ Three-dimensional transesophageal echocardiographic image of a mechanical mitral valve prosthesis. Two valve occluders are seen in the midportion of the image. There is a sewing ring around the valve. This patient developed valve dehiscence with paravalvular regurgitation. A small closure device was placed at the site of the defect along the sewing ring (arrow). A second closure device was being placed at the time of the study (catheter; arrow).

of prior infarcts where myocardium is aneurysmal and hypokinetic, such as the LV apex. The sensitivity and specificity of TTE echocardiography for LV apical thrombi are approximately 95% and 88%, respectively. For TEE, transducer placement is constrained by esophageal anatomy, and the true apex is often not in view, decreasing diagnostic accuracy to visualize apical thrombi. In the left atrium, most thrombi occur in the atrial appendage, particularly in patients in atrial fibrillation or flutter, or with left atrial stasis such as with mitral stenosis. With the posterior anatomic position of the left atrial appendage, atrial thrombi are more optimally seen with TEE (see Fig. 55-5). The sensitivity and specificity of TEE to detect left atrial thrombus near 100%, but care is needed to visualize the appendage in at several planes. Overall, echocardiography is a poor diagnostic tool for pulmonary embolism.³² Rarely, large pulmonary emboli can be imaged in the main pulmonary artery. Often, the only evidence of a large pulmonary embolism is RV enlargement and dysfunction.

In patients with a systemic embolic event, echocardiography identifies a potential cardiac source in up to 30% of cases. Echocardiographic findings associated with increased embolic risk include left-sided thrombi, valve masses (endocarditis), and aortic atherosclerotic disease. Image quality for these abnormalities is improved with TEE, but the potential risks of TEE (conscious sedation, semi-invasive) also should be considered.³³ In addition, systemic embolism can occur if there is paradoxical embolism through an interatrial shunt, such as an atrial septal defect or patent foramen ovale (PFO; Fig. 55-28). Importantly, a PFO itself is not diagnostic for systemic embolism, because this is a common variant that is present in up to 20% of the general population. However, outcome studies in patients with cerebrovascular events suggest an association between stroke and PFO. Early data from PFO device closure trials suggest that for

FIGURE 55-28 ■ Color Doppler imaging shows left to right flow across the interatrial septum, consistent with a patent foramen ovale (PFO). LA, Left atrium; LV, left ventricle; RA, right atrium; RV, right ventricle.

carefully selected patients with history of cryptogenic stroke and PFO, there is evidence of stroke risk reduction from PFO closure over medical management alone. Although a PFO may be seen by color Doppler imaging, agitated saline contrast often provides a more definitive diagnosis (see Fig. 55-7). Valsalva maneuver during the contrast injection can transiently increase right atrial pressure, aiding in diagnosis. Shunting should be seen within three cardiac cycles after right atrial opacification; late contrast that appears after five cardiac cycles typically signifies an intrapulmonary shunt.

Valve vegetations appear echocardiographically as independently mobile masses attached to the upstream side of cardiac valves (e.g., ventricular side of the aortic valve or left atrial side of the mitral valve). Vegetations are most often due to infective endocarditis. Noninfectious etiologies include nonbacterial thrombotic endocarditis and benign masses such as papillary fibroelastomas. Other intracardiac attachment sites for vegetations include indwelling catheters or pacer leads and congenital abnormalities such as ventricular septal defects. With acoustic shadowing from nonbiological material, prosthetic valve endocarditis is often difficult to visualize, and TEE is typically needed to better visualize the valve.

Most tumors in the heart are noncardiac in origin. Primary cardiac tumors in the heart are rare, and the majority of these are benign. Atrial myxomas are the most common primary tumor, often seen as an incidental finding during transthoracic imaging. The most common metastatic tumors include lung, breast, lymphoma, leukemia, stomach, and melanoma, and they can involve the

pericardium, myocardium, and, in rare cases, endocardium. In the case of renal cell carcinoma, direct extension via the inferior vena cava into the right atrium can occur.

CARDIOMYOPATHIES

Congestive Heart Failure

Echocardiography is valuable for the assessment of ventricular systolic and diastolic function, measurement of chamber size and wall thickness, visualization of valve anatomy and function, and clinical evaluation of hemodynamic status in patients with heart failure. In addition, echocardiography can also identify a reversible cause of heart failure, such as valve stenosis or regurgitation. Congestive heart failure owing to ischemic heart disease can be recognized based on regional myocardial dysfunction. However, end stage ischemic disease can result in global biventricular dysfunction, indistinguishable from a primary cardiomyopathy.

Nonischemic, dilated cardiomyopathy is characterized by cardiac chamber enlargement and systolic dysfunction (see Fig. 55-2A). Systolic dysfunction is typically global in nature, but some heterogeneity in regional function may be observed. Ventricular dilation can tether the mitral subvalvular apparatus, resulting in significant mitral regurgitation. Systolic dysfunction and chronic volume overload can also lead to secondary pulmonary hypertension. Although systolic dysfunction is typically the dominant finding, diastolic dysfunction, with increased myocardial wall stress and intracardiac pressures, is also present. Diagnostic indices for dilated cardiomyopathy include systolic and diastolic function, valvular function, and pulmonary pressure estimates.³⁴

Hypertrophic and Restrictive Cardiomyopathy

Hypertrophic cardiomyopathy is characterized by abnormal myocardial thickening. The most common form of hypertrophic cardiomyopathy is asymmetric thickening of the basal interventricular septum (Fig. 55-29). In advanced cases, septal thickening can cause obstruction of LV outflow.³⁵ Severity of LV outflow obstruction can be altered by different loading conditions, with decreased intracardiac volume transiently increasing the severity of obstruction (Valsalva maneuver). Additional findings can include systolic motion of the anterior mitral valve leaflet and chordae into the LV outflow tract. Faulty systolic coaptation of the mitral valve results in posteriorly directed regurgitation. In patients with significant outflow obstruction, pressure gradients in the LV outflow tract can be measured (Fig. 55-30). Other variants of hypertrophy include diffuse, concentric, and apical.

Echocardiography is indispensable for management of hypertrophic cardiomyopathy, and it is used to monitor outflow tract gradients and assess mitral regurgitation severity.³⁶ This information aids timing of surgical or percutaneous myomectomy intervention, and it is used in the cardiac catheterization laboratory to guide percutaneous septal ablation procedures. Intraoperative TEE

FIGURE 55-29 ■ Apical view with prominent hypertrophy of the interventricular septum (*arrow*) in a patient with hypertrophic cardiomyopathy. The aortic valve and ascending aorta (Ao) are seen as well. LA, Left atrium; LV, left ventricle; RV, right ventricle.

FIGURE 55-30 ■ Doppler sample in a patient with hypertrophic cardiomyopathy. The electrocardiogram tracing is shown above the Doppler tracing. During late systole, there is a late-peaking velocity curve with a peak velocity of 4.37 m/sec, which corresponds to a peak pressure gradient of 76.4 mm Hg per the simplified Bernoulli equation.

imaging is used to guide surgical myomectomy, and it can aid in monitoring for procedural complications, such as ventricular septal defect.³⁷ Because hypertrophic cardiomyopathy is associated with angina, arrhythmia, and sudden cardiac death, echocardiographic screening of family members of affected individuals is recommended.

Restrictive cardiomyopathy is uncommon. It is most commonly caused by an infiltrative disease process such as sarcoidosis and amyloidosis. Diastolic function is impaired, with decreased LV compliance and a restrictive

mitral inflow filling pattern.³⁵ Echocardiographic findings can include increased myocardial wall thickness, biatrial enlargement, and elevation in pulmonary arterial systolic pressures; however, these findings are not uniformly present, making restrictive cardiomyopathy difficult to diagnose definitively. Often, additional cardiac diagnostic imaging, such as cardiac magnetic resonance imaging or positron emission tomography, is needed to make the diagnosis.

Cardiac Transplantation

Echocardiography is beneficial to reassess LV function and to optimize intravascular volume status. In end-stage cardiac disease, echocardiography is used in decision-making and clinical management for an LV assist device (LVAD) or biventricular assist devices. For these devices, significant aortic regurgitation, severe mitral stenosis, or interatrial shunts can adversely affect optimal device performance. Functional issues, including assessment for peri-device hematoma, thrombus, and evaluation of RV function can be made, but acoustic shadowing from the device makes complete assessment difficult. Doppler interrogation of the device cannulae allows for an evaluation for partial occlusion or leakage. Serial echocardiography systematically evaluating LV chamber size and aortic regurgitation at a variety of LVAD settings ("ramp study") are used to optimize LVAD settings for individual patients.³⁸ Echocardiographic imaging is also used intraoperatively to aid surgeons in optimal placement of newer, mechanical circulatory support devices, such as percutaneous LVADs.

After cardiac transplantation, echocardiography is useful to monitor for biventricular function, pericardial effusion, and pulmonary hypertension and to assist in biptome placement during cardiac biopsies. Cardiac organ rejection is evidenced by myocardial thickening and diastolic dysfunction in the initial stages, progressing eventually to systolic dysfunction.³⁹ Normal findings after cardiac transplantation include biatrial enlargement from the suturing of the residual native atria to the transplanted heart, discerned as a linear echodensity along the mid-atrial wall. Doppler tracings along the aortic and pulmonic connections allow for assessment of anastomotic stenoses. For long-term follow-up after transplantation, dobutamine echocardiography has shown increased sensitivity over other stress testing modalities to screen for transplant vasculopathy.⁴⁰

PERICARDIAL AND CONSTRICTIVE HEART DISEASE

The pericardium is a thin, dense structure that forms an enclosed space around the heart. The pericardium is difficult to image because it is thin and is often directly in contact with other mediastinal structures, but it may be seen if adjacent fluid, which is echolucent, is present. A small amount of pericardial fluid is a normal finding. Abnormal pericardial findings visualized by echocardiography include fibrinous stranding, tumors, or hematoma.⁴¹

Large amounts of fluid in the pericardial space are abnormal and can cause external cardiac compression or tamponade. The size of a pericardial fluid collection alone does not determine hemodynamic significance. A slowly accumulating pericardial fluid collection can be accommodated, and more than 1 L can accumulate at a low pressure with few overt clinical signs. However, if fluid accumulates rapidly, intrapericardial pressures may exceed intracardiac pressure, leading to hemodynamic compromise or tamponade.

Echocardiographic findings in tamponade include systolic collapse of the right atrial free wall and diastolic collapse of the RV free wall owing to increased intrapericardial pressure (Fig. 55-31).⁴² However, if there is RV hypertrophy or pulmonary hypertension, higher intracardiac pressures can negate chamber collapse. Other echocardiographic findings include inferior vena cava dilation and exaggerated respiratory variation in inflow (>25%) across the atrioventricular valves. However, with clinical tamponade and a large pericardial effusion, the absence of echocardiographic markers for tamponade does not exclude the diagnosis. For example, after cardiothoracic surgery, focal hematomas that are loculated posterior and adjacent to the right atrium can impede atrial inflow. In these patients, suboptimal acoustic windows caused by limitations in patient positioning or surface bandages often limit image quality. If image quality is suboptimal, TEE imaging may be needed. Echocardiographic quantification and localization of pericardial fluid guide clinical decision making regarding approach and feasibility of surgical versus percutaneous pericardial drainage procedures.

FIGURE 55-31 ■ Circumferential pericardial effusion (PEF) with right atrial systolic collapse on the apical four-chamber view (arrow).

Pericarditis is an inflammatory condition in which patients typically have chest pain, diffuse ST elevation on ECG, and an auscultated rub. Concurrent pericardial effusion may or may not be present. Pericardial thickening can occur, but can be difficult to image. With recurrent pericarditis, the pericardium can become thickened and adherent to the myocardium, causing impaired cardiac filling or “constriction.” Other causes of constriction include radiation therapy, prior trauma, or prior cardiac surgery. Exaggerated septal motion during the cardiac cycle signifies equalization of diastolic pressures in the cardiac chambers. Biventricular size and systolic function are usually preserved. Supporting echocardiographic findings for constrictive physiology include increased central venous pressure (inferior vena cava dilation), a prominent y descent on hepatic vein Doppler tracings, and a restrictive filling pattern on transmitral Doppler inflow with rapid early diastolic filling.⁴¹

Differentiation between pericardial constriction and restrictive cardiomyopathy can be challenging.⁴³ Both conditions have increased central venous pressures, usually with preserved systolic function. For restrictive cardiomyopathy, biatrial enlargement and pulmonary hypertension are more prominent findings. For pericardial constriction, marked respiratory variation in ventricular filling is more common, but not definitive. Often, supplementary diagnostic tests are needed to differentiate the diagnoses. These tests include computed chest tomography or magnetic resonance imaging, which allow measurement of pericardial wall thickness. Other diagnostic studies include simultaneous left- and right-sided pressure tracings, with volume loading in the cardiac catheterization laboratory, and myocardial biopsy for infiltrative myocardial disease.

VALVULAR HEART DISEASE

Echocardiography is invaluable for assessment of valve anatomy and function.⁴⁴⁻⁴⁶ Echocardiographic imaging has essentially supplanted the need for invasive valve diagnostics in the catheterization laboratory. Once valve disease is diagnosed, serial echocardiography is used to monitor for onset of adverse hemodynamic effects of valve dysfunction on cardiac function, pulmonary function, and intravascular volume.

Aortic Stenosis

Echocardiography allows for identification of the etiology of aortic stenosis and assessment of valve hemodynamics.⁴⁷ With severe stenosis, leaflet calcification and imaging artifacts often hinder definitive identification of valve morphology. Aortic stenosis severity is evaluated using peak instantaneous transaortic velocities acquired from continuous Doppler ultrasound tracings. Several acoustic windows should be used to ensure that maximal velocity is recorded (see Fig. 55-12). A velocity greater than 4 m/sec indicates severe stenosis, and a velocity of 2.5 to 3 m/sec indicates mild stenosis. Pressure gradients are calculated from the transaortic velocities using the simplified Bernoulli equation. Because transvalvular

pressure gradients vary with volume flow rate, higher pressure gradients and flow velocities will be recorded in the setting of increased stroke volume (i.e., aortic regurgitation), and lower pressure gradients and velocities will be recorded when flow rates are decreased (i.e., LV systolic dysfunction). Aortic valve area (CSA_{AV}) is calculated using the continuity equation where CSA of the LV outflow tract (LVOT) is calculated from LVOT diameter, VTIs in the LVOT are obtained with pulsed Doppler, and the highest aortic Doppler velocity signal is recorded.

$$CSA_{AV} \times VTI_{AV} = CSA_{LVOT} \times VTI_{LVOT}$$

$$\text{rearranged to: } CSA_{AV} = CSA_{LVOT} \times VTI_{LVOT} / VTI_{AV}$$

This equation can be simplified further by substituting peak velocities (V) in place of the VTI measurements:

$$CSA_{AV} = (CSA_{LVOT} \times V_{LVOT}) / V_{AV}$$

A valve area smaller than 1.0 cm² indicates severe stenosis, and a valve area of 1.0 to 1.5 cm² is consistent with moderate stenosis. Diagnostic limitations for echocardiography in evaluating aortic stenosis include measurement variability, optimal alignment of the ultrasound beam to maximize transaortic velocities, and accurate measurement of the LVOT diameter for LVOT area calculation.

Increased afterload in aortic stenosis leads to an increase in myocardial wall stress with LV hypertrophy and impaired diastolic filling. Systolic dysfunction is not common, but it can occur in the late stages of the disease. Transesophageal imaging is usually less optimal for diagnostic evaluation of aortic stenosis as TEE is limited by the inability to optimally align the Doppler ultrasound beam parallel with blood flow across the aortic valve. Direct planimetry of the aortic valve orifice is limited by nonplanar anatomy of the aortic valve, acoustic shadowing, and beam width artifact from leaflet calcification.

Aortic Regurgitation

Common causes of aortic regurgitation include bicuspid aortic valve, endocarditis, and aortic root dilation.¹⁹ The aortic valve and proximal ascending aorta are usually well visualized by TTE. Echocardiographic imaging can aid in surgical planning by determining whether regurgitation is due to aortic root disease or primary valve dysfunction.¹⁹ Doppler echocardiography has high sensitivity and specificity for visualizing regurgitation. Semiquantitative evaluation of regurgitant severity is possible by measuring the vena contracta jet diameter (see Fig. 55-10). Regurgitation can be evaluated qualitatively as mild, moderate, or severe based on the size of the color flow jet relative to the LVOT. With greater than moderate regurgitation, Doppler interrogation of the descending thoracic and proximal abdominal aorta shows holodiastolic flow reversal (Fig. 55-32). Eccentric regurgitant jets that are directed posteriorly may restrict diastolic opening of the anterior mitral valve leaflet. The density of the continuous-wave Doppler signal relative to antero-grade flow is another measure of regurgitant severity.

FIGURE 55-32 ■ Continuous Doppler ultrasound of the abdominal aorta with antegrade aortic flow during systole (S) and holodiastolic flow reversal during diastole (D), consistent with severe aortic regurgitation (arrow).

With acute or severe regurgitation, early diastolic equalization of aortic and LV pressures lead to a steep diastolic deceleration slope of the Doppler envelope and, in severe cases, late-diastolic velocity that approaches zero (see Fig. 55-9).

With significant, chronic aortic regurgitation, LV enlargement or dysfunction owing to increased hemodynamic load can occur. These patients usually develop cardiopulmonary symptoms such as dyspnea, decreased exercise tolerance, and congestive heart failure necessitating valve replacement. In asymptomatic patients, serial echocardiography is recommended to monitor regurgitation severity, ventricular size, and function. Surgery is recommended once adverse hemodynamic effect on LV size or function has occurred (fall in ejection fraction to less than 50% or an end-diastolic diameter that exceeds 70 mm).^{45,46}

Mitral Stenosis

Mitral stenosis is nearly uniformly due to rheumatic valve disease. Echocardiographic appearance of the valve includes commissural fusion, leaflet thickening, calcification, and restricted leaflet motion with diastolic doming of the leaflet in diastole owing to the inability of the valve to open fully (Fig. 55-33). In severe cases, the subvalvular apparatus is also affected with chordal thickening and fusion. Patients with moderate mitral stenosis (mean gradients 5-10 mm Hg) may be asymptomatic at rest, but develop dyspnea with increased cardiac demand, such as exercise or pregnancy. Progressive obstruction of mitral inflow leads to increased left atrial pressure and dilation and increased propensity to develop atrial fibrillation. Rare nonrheumatic causes of mitral stenosis include severe annular calcification and LV inflow obstruction from a vegetation or myxoma.

Peak and mean mitral pressure gradients are estimated from transmitral velocities using the Bernoulli equation. Mitral valve area (MVA) can be calculated from the empirically derived equation $MVA = 220/PHT$, where PHT (pressure half time) is the time duration for the peak

FIGURE 55-33 ■ Parasternal long axis view during diastole with mitral valve calcification and restricted leaflet opening in a patient with rheumatic mitral valve stenosis. There is also diastolic doming of the anterior leaflet (arrow). Ao, Aorta; LA, left atrium; LV, left ventricle.

early mitral inflow pressure gradient to drop by half. Another reproducible measurement for valve area is planimetry of the mitral valve orifice from a parasternal short-axis view (Fig. 55-34). Patients with significant mitral stenosis often have pulmonary hypertension, which can be estimated from the peak velocity of the tricuspid regurgitant jet. When clinical symptoms are discrepant with the hemodynamic severity of mitral stenosis, measuring the rise in pulmonary pressures during exercise echocardiography may be a helpful adjunct.

Echocardiographic valve characteristics that favor successful percutaneous balloon valvotomy include pliable mitral leaflets, minimal commissural fusion, and minimal valvular or subvalvular calcification. Percutaneous valvotomy is not performed if preprocedure TEE demonstrates a left atrial appendage thrombus or if there is greater than moderate mitral regurgitation. During the procedure, 3D echocardiography of the mitral valve during valvotomy aids in catheter placement and assessment of commissural fracture during balloon inflation, gauging the severity of postinflation mitral regurgitation (see Fig. 55-6).

Mitral Regurgitation

The first step in echocardiographic evaluation of mitral regurgitation is determining the cause and mechanism of regurgitation.¹⁹ Echocardiography is integral to visualize leaflet anatomy, assess ventricular geometry, and estimate pulmonary pressures. Common causes of primary mitral valve dysfunction include mitral valve prolapse, endocarditis, and rheumatic disease. In mitral valve prolapse, leaflets are thickened and redundant, and leaflet prolapse greater than 2 mm bowing into the left atrium is diagnostic (Fig. 55-35). Secondary or “functional”

FIGURE 55-34 ■ Parasternal short-axis view allows for direct planimetry of the valve opening in a patient with rheumatic mitral stenosis (area = 1.3 cm²).

FIGURE 55-35 ■ Myxomatous mitral valve disease with redundant mitral valve leaflets and systolic prolapse of the mid-portion into the left atrium beyond the valve annulus. In this patient, prolapse of the posterior mitral leaflet is more prominent (arrow). Ao, Aorta; LA, left atrium; LV, left ventricle.

regurgitation of an otherwise anatomically normal mitral valve can occur with leaflet tethering or dilation of the mitral valve annulus.

Color Doppler mapping allows visualization and assessment of the regurgitant flow disturbance, jet size, direction, and jet eccentricity. Color Doppler has high sensitivity and specificity for detecting mitral regurgitation. A small degree of mitral regurgitation is common, present in up to 80% of normal individuals. By color Doppler, mitral regurgitant flow disturbances range from a small, localized area adjacent to the valve (mild) to a large flow disturbance that fills the entire left atrium (severe). Measurement of the vena contracta at the

FIGURE 55-36 ■ Pulmonary vein tracing in a patient with significant mitral regurgitation. The Doppler signal is positioned in the right upper pulmonary vein (PV; right). Spectral Doppler tracing shows mid-late systolic flow reversal directed away from the transducer (arrow, left).

regurgitant orifice correlates with severity, even with eccentric jets. The shape and direction of the regurgitant jet aid in establishing the mechanism of valve dysfunction. For example, posterior mitral valve leaflet prolapse is usually associated with an anteriorly directed regurgitant jet. Eccentric jets that adhere to the atrial wall usually appear smaller than centrally directed jets; therefore, evaluation of the jet from at least two orthogonal views with careful adjustment of instrument settings is essential.

Greater regurgitation severity leads to increased left atrial pressures and regurgitant flow velocity. Doppler evaluation of the peak early inflow velocity (E wave) and the shape and intensity of the continuous-wave Doppler envelope provide added data on regurgitation severity, with worsened regurgitation leading to higher velocity, denser jets. Another qualitative measure of mitral regurgitant severity is the presence of systolic flow reversal of the pulmonary vein Doppler signal (Fig. 55-36).

Quantitative measures for regurgitation severity are preferred over qualitative assessment alone because color Doppler measures of jet size and flow disturbance are subject to transducer frequency and instrument settings. Quantitative evaluation includes measurement of regurgitant volume using the PISA, and calculation of the regurgitant orifice area. The PISA calculation assumes flow accelerates in a laminar fashion toward a regurgitant orifice, forming concentric hemispheres of isovelocity (see Fig. 55-11).²⁰ The EROA can be calculated once hemisphere surface area, blood velocity at that hemisphere (“aliasing velocity”), and orifice regurgitant velocity are measured. Calculation of EROA is more accurate when the regurgitant orifice is circular and the jet is not eccentric. Quantitative gradation of regurgitation by the American Society of Echocardiography is now incorporated in the AHA/ACC guidelines on valvular heart disease.^{19,45,46}

Progressive mitral regurgitant volume and increased hemodynamic cardiac load can lead to LV chamber enlargement and systolic dysfunction. Serial and echocardiographic measures of ventricular size and systolic function serve as the primary determinants for the timing of intervention in chronic mitral regurgitation. In

asymptomatic patients, surgery is recommended with an LV end-systolic diameter greater than 40 mm, ejection fraction less than 60%, onset of atrial fibrillation, or pulmonary hypertension.^{45,46}

With increased expertise in mitral valve repair and improved outcomes, many experienced surgical centers now advocate for earlier mitral valve repair, even in those with normal LV size and function, when likelihood of a successful repair exceeds 90%. Early intervention mandates a careful echocardiographic evaluation to ensure that regurgitation is severe by established quantitative guideline (EROA ≥ 0.4 cm², regurgitant volume ≥ 60 mL, regurgitant fraction $\geq 50\%$). Close collaboration between the echocardiographer and cardiac surgeon is needed to evaluate likelihood of a successful repair. During surgery, intraoperative TEE is used to evaluate adequacy of repair and identify residual mitral regurgitation.

Tricuspid Valve Disease

Most right-sided valvular disease in adults is secondary to left heart dysfunction. Trace to mild regurgitation of both the tricuspid and pulmonic valves is a normal finding, and it can be seen in more than 80% of normal adults. Significant functional tricuspid regurgitation may be due to pulmonary hypertension (>55 mm Hg), often with concurrent RV and annular dilation.⁴⁸ Other causes of tricuspid regurgitation include endocarditis, carcinoid disease, mediastinal radiation, and injury following pacer lead placement. Echocardiographic features of carcinoid include tricuspid leaflet calcification, thickening, and retraction. A congenital etiology of tricuspid regurgitation includes Ebstein anomaly, with apical displacement of the tricuspid septal leaflet and poor leaflet coaptation. Severe tricuspid regurgitation results in a wide vena contracta (>7 mm) and systolic flow reversal in the hepatic veins (imaged from the subcostal view). With progressive, right-sided volume overload, the right ventricle can become dilated, hypertrophied, and hypokinetic.

Prosthetic Valves

Prosthetic valves fall into two main classes: bioprosthetic and mechanical valves. Because of the sewing ring and struts in prosthetic valves, the functional valve area of prosthetic valves is smaller than with native valves, resulting in relatively higher antegrade velocities.⁴⁹ Knowledge of the individual flow dynamics of the different valve types is important to discriminate normal from abnormal transvalvular flow and function. Expected transvalvular velocities, areas, and gradients are dependent on valve size, patient size, valve type, and valve position. Optimal echocardiographic evaluation is often hindered by valve positioning, reverberations from artificial materials that hinder visualization of the valve occluders, and acoustic shadowing from artificial materials (see Fig. 55-3). This is particularly problematic when evaluating mitral prostheses for regurgitation because of shadowing of the left atrium. Transesophageal echocardiography (images posterior to the heart with improved image quality) is often needed for more definitive assessment (Fig. 55-37).⁵⁰

FIGURE 55-37 ■ St. Jude mechanical prosthesis (arrow) in the mitral position with acoustic shadowing of the left ventricle during TEE imaging. In patients with mitral prostheses, TEE is often needed to definitively evaluate for valve dysfunction, endocarditis, and regurgitation into the left atrium. LA, Left atrium.

For any prosthetic valve, it is not uncommon to see a small amount of regurgitant valvular flow. In the immediate postoperative period, tiny paravalvular regurgitant jets are common and usually resolve over time. With a single tilting disk valve, there is an asymmetrical flow profile with a major and minor antegrade flow identified and an eccentric, small regurgitant jet. Bileaflet mechanical valves have complex fluid dynamics with antegrade flow seen via two minor orifices corresponding to each leaflet, and one central major orifice. During valve closure, two small, central intersecting regurgitant jets are normally seen. Estimation of transvalvular gradients is relatively reliable for bioprosthetic valves. However, with mechanical valves, flow is heterogeneous across the entire orifice face, and high local velocities at the smaller leaflet orifices can lead to overestimation of the transvalvular gradient. Because of the absence of prosthetic material, the appearance of homograft and stentless tissue aortic valves may be echocardiographically indistinguishable from native valves.

Because prosthetic valve hemodynamics vary depending on patient habitus and valve type, a baseline echocardiogram (2-3 months) following surgery is recommended. Subsequently, serial examinations are typically not necessary unless the patient develops new cardiopulmonary symptoms or valve dysfunction is suspected. Complications, including endocarditis, pannus, or thrombus that impairs disk motion, can be diagnosed accurately with echocardiography. Because of improved image quality and more optimal transducer placement, TEE echocardiography is nearly always needed in the evaluation of prosthetic valve dysfunction.

Endocarditis

Used in combination with clinical and bacteriological data, echocardiography provides invaluable information

in the evaluation for endocarditis.⁵¹ The risk of endocarditis is highest in patients with valve prostheses, native valve disease, congenital heart disease, or a clinical risk factor, such as intravenous drug use. Major echocardiographic diagnostic criteria include echodense masses adherent to valve leaflets (vegetations) or endocardial surfaces, paravalvular abscesses, and prosthetic valve dehiscence (Fig. 55-38).

When endocarditis is suggested by predisposing factors, fever, sepsis, or embolic events, TTE is the initial procedure of choice. TTE allows for better manipulation of the transducer to evaluate possible fistulas and abnormal communications. However, although the specificity for TTE is adequate ($\approx 91\%$ - 98%), the sensitivity of TTE is relatively poor ($\approx 36\%$ - 90%) with more studies at the lower end of the spectrum. Therefore, patients with a negative transthoracic study, but in whom clinical suspicion for endocarditis is significant should also receive a TEE.⁵² Diagnostic accuracy for TEE is higher, and TEE more readily images complications of endocarditis. Regardless, if results of echocardiographic evaluation for endocarditis are negative, but clinical suspicion remains high, repeated echocardiography should be considered because a subsequent study result may be abnormal with disease progression.

Limitations for echocardiography and endocarditis include an inability to distinguish between acute and chronic lesions, vegetations and thrombus, reverberations from calcifications or prosthetic materials, and non-bacterial thrombotic lesions, as can be seen with systemic lupus erythematosus. False-positive findings include normal leaflet thickening, Lambl excrescences on the aortic valve, mitral leaflet redundancy resulting from myxomatous disease, partial flail leaflets, leaflet calcification, and degenerative changes.

FIGURE 55-38 ■ Native aortic valve endocarditis in a patient with severe aortic regurgitation and cardiogenic shock. There is a large, mobile vegetation that is adherent to the aortic valve and that prolapses into the LV outflow tract (arrow). Ao, Aorta; LA, left atrium; LV, left ventricle; Veg., vegetation.

Common complications of endocarditis include involvement of other valves, leaflet perforation, paravalvular abscess, fistula development, and coronary embolization. Valve dysfunction associated with endocarditis usually leads to regurgitation. As with native valves, endocarditis of a bioprosthetic valve is often evidenced by vegetations. With mechanical valves, vegetations are less common. Instead, infection often causes valve instability, with dehiscence, paravalvular leak, or abscess. A paravalvular abscess in the aortic position may extend to the anterior mitral valve leaflet with involvement of the mitral-aortic intervalvular fibrosa (Fig. 55-39). Because of its communication with the LV cavity, flow into and out of the pseudoaneurysm can be demonstrated by color Doppler imaging. Infection that involves the aortic sinuses can lead to sinus of Valsalva aneurysm and rupture, with Doppler interrogation demonstrating flow into the cardiac chamber adjacent to the affected sinus.

AORTIC DISEASE

Transthoracic echocardiography is reliable in imaging aortic anatomy throughout most of the thoracic and proximal abdominal aorta. Standard aortic diameter measurements are taken from the aortic valve annulus, sinuses, sinotubular junction, ascending aorta, arch, and descending thoracic aorta.⁵³ Nonoblique imaging is essential for accurate measurement of internal aortic dimensions at end diastole. Image resolution with TTE is often limited by the aorta's posterior position and overlying air-filled structures such as the trachea and lungs. In addition, distance from the chest wall to the aorta

FIGURE 55-39 ■ Pseudoaneurysm of the mitral-aortic intervalvular fibrosa (arrow) in a patient with a mechanical aortic valve, imaged by transesophageal echocardiography. Systolic flow is seen by color Doppler into the left ventricle (LV) outflow tract. Ao, Aorta; LA, left atrium.

hinders optimal image resolution. Therefore, TEE, with the shorter distance between the transducer and the aorta and better ultrasound penetration, is often needed to complete a full echocardiographic aorta evaluation. Computed tomography and magnetic resonance imaging allow for better spatial imaging of the aorta; however, echocardiography allows for imaging in the absence of radiation or contrast exposure. Echocardiography also has the advantage of portability and allowing for identification of concurrent pericardial fluid and aortic regurgitation. Importantly, data are more readily available as limited imaging of the aorta is routinely performed on most transthoracic studies.

Asymptomatic dilation of the ascending aorta is associated with atherosclerosis, systemic hypertension, bicuspid aortic valves, and Marfan disease. Marfan disease is associated with dilation of the aortic sinuses with effacement of the sinotubular junction. Patients with aneurysmal dilation of the sinuses or ascending aorta are at increased risk of dissection and aortic rupture. Therefore, serial echocardiography is used to monitor for progressive enlargement, to time referral for prophylactic surgical repair.⁵³

Atherosclerotic disease is more easily imaged with TEE, in which the severity and extent of disease can be readily imaged along the length of the thoracic and proximal abdominal aorta (Fig. 55-40). Common findings include atherosclerotic plaques, ulceration, associated dilation, and adherent mobile thrombi, which are all considered potential sources of distal embolic disease. Intraoperative use of TEE and/or epiaortic scanning with a sterile transducer to localize atherosclerotic plaques directs optimal placement of the aortic cannula for the arterial bypass circuit and for aortic cross-clamping.

FIGURE 55-40 ■ Mild atherosclerosis (arrows) of the descending thoracic aorta (DA) imaged by transesophageal echocardiography. Calcification within the atherosclerotic plaque causes acoustic shadowing distally in the far field.

In aortic dissection, the flap appears as a thin, mobile echodensity within the aortic lumen (Fig. 55-41). The false lumen can contain thrombus, localize, or propagate distally. Color flow Doppler can be used to identify entrance and exit points to the false lumen. Associated findings with dissection can include intramural hematoma, extension of the dissection into the branch vessels or a coronary artery with resulting regional wall motion abnormalities, pericardial or pleural effusion, aortic root dilation, and flail aortic leaflet with aortic regurgitation. The sensitivity for TTE to detect aortic dissection ranges between 29% and 80%, limited by beam width artifacts and reverberations that increase false-positive results. The specificity of TTE is also low, because of difficulty imaging the posteriorly located aorta. In the hands of an experienced operator, TEE provides improved image quality and more complete evaluation of the length of the thoracic aorta, with sensitivity and specificity approaching 100%. Following surgical intervention, serial echocardiography is used to monitor for recurrent disease, evaluate the proximal and distal graft anastomotic sites, and assess prosthetic valve function. Computed tomography, TEE, and cardiac magnetic resonance imaging have equivalent diagnostic accuracy for aortic dissection.

CONGENITAL HEART DISEASE

Echocardiography is a key diagnostic modality in patients with congenital heart disease.⁵⁴ Indications for echocardiography include diagnosis, monitoring for hemodynamic progression of lesions on cardiac function, and anatomic definition or guidance for palliative or reparative interventions. Echocardiography accurately detects intracardiac shunts with Doppler interrogation and agitated saline contrast studies. By comparing the volume flow rates across the pulmonic and aortic valves, quantitation of the pulmonic-to-systemic shunt ratio can also be estimated.

For atrial septal defects, echocardiography allows distinction between secundum, primum, and sinus venosus defects with demonstration of left-to-right flow across the atrial septum on color Doppler flow imaging. Other

FIGURE 55-41 ■ A dissection flap is seen within an enlarged aorta, imaged by transesophageal echocardiography. The true lumen (TL) is visualized with color Doppler imaging.

findings associated with atrial septal defects include right heart enlargement, hypertrophy, and pulmonary hypertension. Three-dimensional echocardiography allows for improved spatial resolution of the inter-atrial septum and aids in decision making regarding size and placement of defect for percutaneous versus surgical closure. Ventricular septal defects can be identified by Doppler flow across the interventricular septum. In adults, most ventricular septal defects are small, with high-velocity left-to-right systolic flow and a relatively small shunt volume.

Bicuspid aortic valves are the most commonly occurring congenital abnormality (Fig. 55-42). Aortic root dilation is common in these patients, and serial echocardiography is indicated once diagnosed to monitor for progressive valve dysfunction and aortic dilation (Fig. 55-43). In patients with aortic coarctation, transthoracic

imaging can demonstrate the aortic narrowing. Doppler examination of the thoracic aorta shows increased antegrade flow velocity in the region of the coarctation, with antegrade aortic flow that persists into diastole. With a patent ductus arteriosus, color Doppler may show the communication between the pulmonary artery and aorta, and, if shunt flow into the pulmonary artery is large enough, may demonstrate aortic diastolic flow reversal.

The most common complex congenital heart disease seen in the adult population is tetralogy of Fallot. Most patients with tetralogy of Fallot have undergone surgical repair with ventricular septal defects closure and enlargement or patch repair of the RV outflow tract. Serial echocardiography is performed to monitor for pulmonic regurgitation related to the transannular pulmonic patch and RV size and function; this necessitates repeat surgical intervention. In patients with previous surgical repair of complex congenital heart disease, echocardiography is a key tool in monitoring for long-term complications of prior palliative or corrective surgeries. With knowledge of the previous surgical procedures and a careful and meticulous examination, anatomy and physiology are usually well demonstrated. However, in complex cases, other imaging procedures, including magnetic resonance imaging and cardiac catheterization, may be needed for complete patient evaluation. Prior operative reports often greatly assist the echocardiographer in interpreting the nature of congenital repair and in identifying complications.

Interventional cardiology is a subspecialty of medicine that treats a variety of cardiovascular disorders using catheter-based therapeutics. Despite its humble beginnings in 1977, interventional cardiology now includes an array of procedures and techniques for the treatment of ischemic, valvular, and congenital heart disorders. The growth and maturation of the discipline have closely paralleled the rapid influx of new technologies and pharmacotherapeutics. This chapter will review the historical development in interventional cardiology, indications and techniques, and the evolution of the devices and medications used during these procedures.

HISTORICAL PERSPECTIVE

After the refinement of diagnostic coronary angiographic catheters by Sones, Judkins, and Abrams in the 1950s, the radiologist Charles Dotter performed the first endovascular dilation of a stenotic artery for therapeutic purposes in 1964.¹ Peripheral arterial lesions were treated with progressive coaxial catheter dilation to improve blood

flow. Complications including hematoma formation and distal embolization were common, and this technique, referred to as “dottering,” did not gain favor in the United States. However, European investigators continued to study and modify the technique. One such physician, Andreas Gruentzig, modified the Dotter multiple catheter system and developed a double-lumen catheter with a distensible balloon on the end that provided circumferential rather than coaxial pressure on the atherosclerotic plaque. Inflation of the angioplasty balloon within the atherosclerotic plaque led to fissuring and cracking of the intima with stretching of the media and adventitia (Fig. 56-1).

Gruentzig performed the first *peripheral* balloon angioplasty in 1974 and then the first human coronary angioplasty in the operating room during elective coronary artery bypass surgery. When Gruentzig performed the first *percutaneous* transluminal coronary angioplasty (PTCA) in September 1977, the discipline of interventional cardiology was born.²

Initially, balloon angioplasty was offered as an alternative to coronary artery bypass surgery in symptomatic

FIGURE 56-1 ■ Mechanism of lumen enlargement with angioplasty. (From Willerson JT: *Treatment of heart diseases*, New York, 1992, Hower Medical.)

patients with focal, proximal stenoses. Dilation of these arteries was usually associated with significant improvement in angina and in objective measures of ischemia.³ However, the application of PTCA was limited to a small fraction of coronary lesions, because first-generation fixed-wire balloons lacked the ability to be steered and the profile needed to traverse distal and tortuous vessels. Easier to use over-the-wire and rapid-exchange systems began to replace the initial fixed balloon-on-wire system developed by Gruentzig. The development of conformable, low-profile balloons facilitated dilation of distal lesions in tortuous and calcified vessels.

The major limitations of balloon angioplasty—abrupt vessel closure and restenosis—were addressed by the development of new devices in the late 1980s and early 1990s. With the introduction of atherectomy devices, laser balloon catheters, and endovascular stents, the more generic term *percutaneous coronary intervention* (PCI) replaced the term PTCA and referred to any catheter-based procedure intended to enlarge the lumen of a stenotic vessel. Atheroablative techniques such as directional and rotational atherectomy and excimer laser angioplasty were marketed initially as replacements for balloon angioplasty. Although these techniques improved technical success in certain high-risk subsets such as fibrocalcific and bifurcation stenoses, they were technically difficult to perform, did not have a major impact on restenosis, and have largely been abandoned as stand-alone therapies.

The widespread use of endovascular prostheses, or stents, unequivocally improved the acute safety and long-term efficacy of catheter-based treatment. As a result, more than 1 million PCIs are now performed each year in the United States to alleviate symptoms and reduce adverse cardiac events.⁴ Stents were originally approved to seal dissection flaps and reverse acute vessel closure after PTCA by inhibiting elastic recoil in the arterial wall. The Gianturco-Roubin coil stent was the first such device approved in the United States, and it was approved on the basis of its ability to stabilize dissections and thus reduce the incidence of abrupt vessel closure and early complications.⁵ In 1994, the balloon-expandable Palmaz-Schatz slotted tube stent was approved for elective use

after two randomized trials showed significant reductions in angiographic restenosis.^{6,7}

Thus, by the end of the millennium, stents became the default technology for catheter-based therapy, with 70% to 80% of all patients undergoing PCI receiving a stent. Despite the salutary effects of stents, restenosis still occurred in 10% to 30% of patients, who usually presented with recurrent ischemia. The use of adjunctive intravascular brachytherapy after balloon dilation of in-stent restenosis greatly reduced the need for subsequent revascularization procedures in patients who suffered restenosis despite stents, but it was associated with no significant impact on long-term outcome.⁸ As a result, this technology has been largely abandoned for use in coronary arteries.

In 2004, the U.S. Food and Drug Administration (FDA) approved the use of drug-eluting stents (DESs) that elute either sirolimus or paclitaxel into the vessel directly from a polymeric coating on the stent. The introduction of this technology dramatically reduced restenosis rates. Some of the initial enthusiasm for the DES was tempered by reports suggesting a higher incidence of very late stent thrombosis with DESs compared with bare metal stents (BMSs). This led to a more individualized approach to DES usage, with a BMS used in patients who had a high risk of hemorrhage or poor compliance with dual antiplatelet therapy. Presently, a DES is used in approximately 60% to 70% of all PCIs in the United States. Second-generation DESs featuring newer drugs, polymers, and stent delivery systems are now approved for use and are associated with lower rates of restenosis, stent thrombosis, and myocardial infarction compared with first-generation technology. Stents with bioabsorbable polymer coatings and others where the scaffolding is completely biodegradable are in use.^{9,10}

PERCUTANEOUS CORONARY INTERVENTION PROCEDURES

Coronary intervention, like diagnostic angiography, begins with placement of a vascular access sheath in the femoral, brachial, or radial artery. Although choice of access site is at the discretion of the operator, most interventional procedures are performed using the femoral artery.¹¹ Radial artery access has been the default strategy for many years in some countries and is gaining popularity in the United States. This approach has been associated with improved outcomes, particularly in ST-segment elevation myocardial infarction (STEMI), reduced vascular complications, and greater patient satisfaction.^{12,13} Procedural success rates are comparable across all access sites, but radiation exposure and procedure times are slightly longer with brachial or radial procedures.¹⁴ Use of the radial access site is limited by the small size of the artery, radial, subclavian, and aortic tortuosity, as well as operator familiarity and experience.

Arterial access is obtained via percutaneous puncture of the wall of the artery with a hollow needle.¹⁵ A guide-wire is advanced through the lumen of the needle or catheter, and the needle or catheter is removed. A vascular sheath is then inserted over this wire. Large-lumen

FIGURE 56-2 ■ Angiogram during percutaneous coronary intervention of the left anterior descending artery.

guiding catheters are then advanced through the arterial sheath and to the ascending aorta over a wire placed in the aorta. The guidewire is removed, and selective cannulation of the coronary arteries or bypass conduits is undertaken. If a stenosis is repaired, a 0.014-inch wire is used to traverse the stenosis, and the equipment used to treat the stenosis is advanced coaxially over this wire into the vessel (Fig. 56-2).

All PCI procedures require administration of antiplatelet and anticoagulant medications during the procedure. Unfractionated heparin, low-molecular-weight heparin, or the direct thrombin inhibitor bivalirudin are commonly used anticoagulants to support PCI. Aspirin is administered before the procedure, and an additional oral antiplatelet agent (clopidogrel, ticagrelor, or prasugrel) or an intravenous agent (eptifibatide, tirofiban, or abciximab) is also administered before, during, or after the procedure in most circumstances. The optimal timing and combinations of these agents in various clinical scenarios is an important consideration for PCI procedures but is beyond the scope of this discussion.

PCI for Unstable Angina and Non-ST-Segment Elevation Myocardial Infarction

Current guidelines support the use of an early invasive management strategy with early coronary angiography for patients with unstable angina or non-ST-segment elevation myocardial infarction (NSTEMI) who are at moderate or high risk for reinfarction or death. Those with positive cardiac biomarkers, ST-segment changes on 12-lead electrocardiogram, or clinical parameters such as congestive heart failure, refractory angina, or arrhythmia gain particular benefit.¹⁶ This strategy involves early

administration of antithrombotic and antiplatelet medications as well as early angiography for further risk stratification. When the coronary anatomy is suitable, revascularization with coronary artery bypass graft (CABG) or PCI is performed unless there is a strong contraindication. Typically, among moderate- and high-risk patients undergoing angiography for unstable angina or NSTEMI, approximately 30% are managed without revascularization, 55% to 60% with PCI, and 10% to 15% with CABG.¹⁷ Patients at low clinical risk can be treated with a selective invasive strategy. Revascularization can be reserved for patients with high-risk noninvasive test results or recurrent symptoms.

PCI for ST-Elevation Myocardial Infarction

The benefits of mechanical or pharmacologic reperfusion therapy in the setting of acute STEMI are well established. In comparison with PTCA alone, PCI with stent placement significantly reduces the incidence of death and ischemic target vessel revascularization, and the benefit is maintained for up to 5 years in patients with acute MI.¹⁸⁻²⁰ PCI in this setting is called primary PCI and has been shown to effectively reestablish normal epicardial coronary perfusion in more than 90% of patients. Assuming treatment times remain short and the artery can be opened expeditiously at an experienced center, PCI has been shown to be superior to fibrinolytic therapy even if transport is required.²¹ Treatment times are important operator and hospital quality benchmarks. The time from first medical contact to first device activation within the artery should be 90 minutes or less and less than 120 minutes for patients who require transfer to a PCI capable facility.^{22,23}

Long-term patency rates exceed 85%, and the risks of reinfarction and death are significantly reduced with PCI compared with fibrinolytic therapy.^{1,24-26} Initial reports suggested harm when combining fibrinolysis and PCI, but among the 30% to 50% of patients in whom fibrinolytic therapy does not restore arterial patency, so-called subsequent rescue PCI is associated with improved outcomes compared with fibrinolytic therapy alone.^{27,28} A pharmacoinvasive strategy has been advocated for patients with an anticipated delay to primary PCI. With this strategy, fibrinolytic therapy is administered and the patient is transported to a facility for rescue PCI if fibrinolytic therapy fails or for routine angiography and elective PCI 3 to 24 hours after fibrinolysis.^{29,30} Additional fibrinolytic therapy at the time of immediate PCI is called facilitated PCI and is associated with adverse consequences. Facilitated approaches, in which the intent is to improve outcomes of the PCI procedure with concurrent fibrinolytic therapy, should be distinguished from pharmacoinvasive strategies, in which the intent is to improve outcomes of fibrinolytic therapy by using adjunctive PCI.

Patients who develop cardiogenic shock in the setting of acute myocardial infarction (MI) also seem to benefit from immediate revascularization with PCI or CABG. Improved survival at 6 months has been shown in a randomized trial comparing immediate revascularization, using either PCI or CABG, with initial medical

stabilization using fibrinolytic therapy, delayed revascularization, or both. However, among the subset of patients older than 75 years, reduced survival was noted when immediate revascularization was used compared with medical stabilization followed by delayed revascularization.³¹

PCI for Chronic Stable Angina

Although medical therapy is preferred in patients with minimal symptoms and only a small area of ischemic myocardium, patients with large amounts of ischemic but viable myocardium in jeopardy have better anginal control if coronary revascularization is performed. Patients who are asymptomatic or whose symptoms can be controlled with medications, but who have high-risk noninvasive test findings, have been shown to have lower rates of death or MI when treated with revascularization compared with medical therapy alone.^{32,33}

The Clinical Outcomes Utilizing Revascularization and Aggressive Drug Evaluation (COURAGE) trial found that in the initial management of stable coronary artery disease (CAD), PCI and medical management did not significantly differ in their reduction of death, MI, or adverse cardiovascular events.³⁴ By 5 years, there was no significant difference in angina symptoms, although PCI was associated with earlier palliation of angina. The American College of Cardiology/American Heart Association (ACC/AHA) guidelines for PCI, however, suggest that asymptomatic or minimally symptomatic patients with coronary lesions that are 50% stenosed or greater in one or two arteries undergo PCI if there is a high likelihood of success and a low risk of morbidity and mortality, and if the arteries supply a moderate or large area of viable myocardium.^{32,35} Thus, the decision to undergo elective PCI is largely based on the degree of myocardium at risk and failure of initial medical therapy.

Multivessel PCI

The comparative usefulness of multivessel PCI versus CABG has been the subject of significant debate. Whether to perform PCI or CABG is often based on the complexity, severity, and extent of disease, as well as on patient risk factors for ischemia and surgical complications. Perceived benefits of CABG compared with PCI are described in [Box 56-1](#). Various lesion subsets have been evaluated in registries that suggest a benefit for CABG compared with PTCA in patients with three-vessel disease or severe stenosis of the proximal left anterior descending artery.³⁶ Randomized comparisons have been performed of CABG and PTCA, BMS and DES ([Table 56-1](#)). The largest comparison of PTCA and CABG was the Bypass Angioplasty Revascularization Investigation (BARI) trial, which demonstrated that 5-year survival and survival free of Q-wave MI did not differ significantly between the PTCA and CABG groups (86.3% vs. 89.3% and 78.4% vs. 80.4%, respectively; $P = 0.19$). On the other hand, patients randomized to CABG were much less likely to require repeat revascularization. Nonetheless, 69% of patients initially assigned to PTCA avoided CABG over a 5-year period.³⁷ In this trial, CABG

BOX 56-1 Benefits of Coronary Artery Bypass Graft Surgery and Benefits of Percutaneous Coronary Intervention

CORONARY ARTERY BYPASS GRAFT

- Fewer subsequent procedures and hospitalizations
- More complete symptom relief at 1 and 3 years
- More complete initial revascularization
- Improved survival and fewer repeat procedures among diabetic patients and those with complex disease
- Established benefit in left main coronary disease

PERCUTANEOUS CORONARY INTERVENTION

- Can be performed among patients with increased peri-operative risk
- Quicker recovery from initial procedure
- Most patients asymptomatic at 1- and 3-year follow-ups
- With stents, 80% to 90% of patients do not require coronary artery bypass graft surgery

provided an important advantage over PTCA for diabetic patients ($n = 353$).³⁸ At 5-year follow-up, all-cause mortality was 19.4% in the 180 diabetic patients assigned to CABG, and 34.5% among the 173 patients assigned to PCI ($P = 0.003$). In a registry of patients screened but not randomized in the BARI trial, long-term follow-up demonstrated no significant difference in mortality between diabetic patients undergoing CABG and those assigned to PCI.^{39,40} In contrast to the randomized trial, patients in the BARI registry had their initial revascularization strategy chosen by their physicians, which may have been the reason for the difference in outcome.

Several studies have examined outcomes of multivessel BMS placement compared with CABG (see [Table 56-1](#)). Meta-analysis of the four major randomized trials comparing BMS and CABG revealed a 5-year safety profile for PCI that is similar to that for CABG. Lower repeat revascularization rates were found among the CABG patients (29.0% vs. 7.9%, respectively; hazard ratio [HR], 0.23; 95% confidence interval [CI], 0.18-0.29; $P < 0.001$) ([Fig. 56-3A](#)) with no difference in rates of death, stroke, or MI (see [Fig. 56-3B](#)). No subgroup, including diabetic patients and those presenting with three-vessel disease, was found to have a selective benefit with CABG.⁴¹

It was postulated that reductions in repeat revascularization rates associated with DES would lower adverse events after multivessel PCI sufficiently to favor this strategy over CABG. The Synergy between Percutaneous Coronary Intervention with TAXUS and Cardiac Surgery (SYNTAX) trial evaluated patients with three-vessel or left main coronary artery (LMCA) disease randomizing them to paclitaxel-eluting stents or CABG.⁴² Three- and five-year follow-up data from SYNTAX demonstrated higher rates of major adverse cardiovascular events with paclitaxel-eluting stents compared with CABG (28.0% vs. 20.2%; $P < 0.001$ at 3 years and 37.3% vs. 26.9%; $P < 0.0001$ at 5 years).^{43,44} Cardiac death was less with CABG (5.3% vs. 9.0%; $P = 0.003$) as was MI (3.8% vs. 9.7%; $P < 0.001$) and repeat revascularization (13.7% vs. 25.9%; $P < 0.001$).

TABLE 56-1 Randomized Clinical Trials Comparing Coronary Artery Bypass Graft (CABG) and Percutaneous Coronary Intervention (PCI)

Clinical Parameters						
	Trial	Mortality & MI	Angina Relief	Repeat Revascularization	Stroke	Cost Assessment

Adapted from Levine GN, Bates ER, Blankenship JC, et al: 2011 ACCF/AHA/SCAI guideline for percutaneous coronary intervention. A report of the American College of Cardiology Foundation/American Heart Association Task Force on Practice Guidelines and the Society for Cardiovascular Angiography and Interventions. *Circulation* 124:e574–e651, 2011.

The SYNTAX score, developed in this trial, is based on the angiographic complexity and extent of disease. Using this score, patients' coronary disease could be divided into three categories, low (0–22), intermediate (23–32) and high (≥ 33). When stratifying outcomes according to SYNTAX score, adverse outcomes at 5 years for CABG were not significantly different across these strata (28.6%, 25.8%, 26.8% for low, intermediate, and high SYNTAX scores, respectively). The comparative outcomes with PCI versus CABG, however, differed significantly. For patients with low SYNTAX scores, no significant differences in outcomes were noted for CABG versus PCI, but in patients with intermediate and high SYNTAX scores, the rates of MI and repeat revascularization were significantly higher with PCI.

The largest trial of patients with diabetes and multivessel disease was Future Revascularization Evaluation in Patients with Diabetes Mellitus: Optimal Management of Multivessel Disease (FREEDOM), which randomized 1900 patients, 83% of which had three-vessel disease, to either PCI with DESs or CABG.⁴⁵ The 5-year rates of the primary outcome (a composite of death, nonfatal MI, and nonfatal stroke) were significantly reduced with CABG compared with PCI (18.7% vs. 26.6%; $P = 0.005$) because of increased rates of death and MI in the PCI group (16.3% vs. 10.9%; $P = 0.049$ and 13.9% vs. 6.0%; $P < 0.001$ in the PCI and CABG groups, respectively), whereas the rates of stroke were significantly higher with CABG at 5 years (2.4% vs. 5.2%; $P = 0.03$).⁴⁵ The benefit of CABG over PCI among diabetic patients with multivessel disease was present regardless of SYNTAX score, implying CABG is superior to PCI in diabetics with

multivessel coronary disease regardless of anatomic complexity.

Left Main-Stem Disease

Stent placement in the LMCA can be performed with high rates of procedural success. As is the case with multivessel PCI, PCI of the LMCA is associated with higher rates of repeat revascularization. The DES has rapidly and largely replaced the BMS for PCI of the unprotected LMCA. However, PCI is still chosen less frequently than CABG for unprotected left main revascularization. Registries describing outcomes after DES implantation or CABG for LMCA stenosis have demonstrated higher rates of repeat revascularization with PCI and lower mortality rates with CABG.^{46,47} It is unknown whether differences in patient risk and angiographic parameters affect these results. A subgroup analysis of the SYNTAX trial involving 705 patients with LMCA disease did not show a significant difference in 12-month rates of major adverse cardiovascular events with PCI (15.8%, vs. 13.7% with CABG; $P = 0.44$), but PCI had a significantly higher rate of repeat revascularization (13.5%, vs. 5.9% with CABG; $P < 0.001$).⁴² The increased rate of repeat revascularization with PCI was countered by a significantly lower rate of stroke (0.3%, vs. 2.7% with CABG; $P = 0.01$). These results remained consistent at 5-year follow-up.⁴⁴

The ACC/AHA guidelines for PCI strongly recommend (class I) CABG for patients with significant ($\geq 50\%$ diameter stenosis) left main stenosis. However, PCI for LMCA disease is recommended (class IIa) as a reasonable alternative to CABG in select patients with coronary

FIGURE 56-3 ■ Kaplan-Meier event-free survival analysis of repeat revascularization (**A**), and death, stroke, or myocardial infarction (**B**). CABG, Coronary artery bypass graft surgery; PCI, percutaneous coronary intervention.

anatomy predictive of a low PCI complication rate and good outcome (such as SYNTAX score ≤ 22 , ostial LMCA disease), as well as those patients with an increased risk of adverse surgical outcomes.⁴⁸ The updated Appropriate Use Criteria for Coronary Revascularization gave an “uncertain” rating to PCI for isolated left main stenosis or left main stenosis with low CAD burden (i.e., additional one- or two-vessel disease, low SYNTAX score); PCI for left main disease with additional, intermediate-to-high CAD burden (three-vessel disease, chronic total occlusion, high SYNTAX score) was rated “inappropriate.”⁴⁹ However, CABG for LMCA disease, with or without additional CAD burden, was rated “appropriate.” Therefore, the decision to treat left main CAD with PCI or CABG, similar to all patients with stable CAD, should depend on multiple factors, including coronary anatomy and relative surgical risk.

Elective PCI and Noncardiac Surgery

The incidence of perioperative cardiac events ranges from 2% to 6%, depending on the type of surgery performed and the patient’s clinical risk factors. Most studies have focused on patients requiring vascular surgery. It is recommended that patients with three or more clinical risk factors and poor functional capacity (class IIa) undergo further testing before vascular surgery. Those with one or two clinical risk factors and poor functional capacity undergoing intermediate-risk surgery or who have good functional capacity prior to vascular surgery (class IIb) may also undergo testing.⁵⁰ A study of patients with clinically significant CAD randomized to either revascularization or no revascularization prior to major elective vascular surgery found no difference in mortality rate at 2.7 years.⁵¹ The current ACC guidelines recommend PCI only for those who would receive a benefit of revascularization independent of surgery. Further cardiac testing is recommended prior to surgery only if it will change management.⁵² Moreover, surgery soon after PCI may be associated with adverse outcomes. Because uninterrupted dual antiplatelet therapy (DAPT) is necessary after stent implantation, bleeding complications may result in the perioperative period, or there may be catastrophic consequences caused by stent thrombosis resulting from discontinuation of antiplatelet medications or from a hypercoagulable state induced by surgery.

In a small cohort of 192 patients, the highest risk of cardiovascular events in the postoperative period occurred in those who discontinued DAPT prematurely after PCI (30.7% vs. 0%; $P = 0.026$).⁵³ Moreover, surgery at less than 6 weeks after stent placement has been associated with a higher incidence of adverse events such as death and MI⁵⁴ and should be avoided when possible.

COMPLICATIONS OF PERCUTANEOUS CORONARY INTERVENTION

Death

Mortality can occur during PCI from a variety of complications, including anaphylactoid reactions, acute MI, pericardial tamponade, stroke, or vascular trauma. Since stents have been used, mortality rates associated with elective coronary intervention have fallen to less than 0.3%.^{55,56} In fact, most elective PCI procedures are considered outpatient procedures and an increasing proportion of patients are discharged on the same day as the PCI procedure. Patients at higher risk include older adults, those undergoing emergency PCI or PCI on saphenous vein grafts, and those with decompensated heart failure or reduced cardiac ejection fraction, end-stage renal disease, cardiogenic shock, or acute MI.^{24,57}

Emergency Bypass Surgery

Although technical improvements allowed PTCA success rates of approximately 60%,²⁵ successful PTCA was limited by an inability to expand balloons in fibrocalcific lesions. In addition, the barotrauma associated with

dilation of stenotic lesions led to medial dissection and many of the complications of angioplasty. Abrupt vessel closure occurred in approximately 5% of cases and was caused by a combination of factors, including arterial dissection, vascular recoil, vasospasm, and thrombosis. Flow-limiting dissections and thrombosis were treated with prolonged balloon inflations and aggressive anticoagulation, but despite these treatments, emergency bypass surgery was required in almost 50% of cases of abrupt vessel closure. In the pre-stent era, emergency surgery was required in approximately 3% to 5% of procedures,^{25,58,59} with significantly greater morbidity and mortality rates than seen with elective bypass surgery.⁶⁰⁻⁶² The widespread use of stents has led to an evolution of the role of the cardiac surgeon in managing acute complications of PCI. The need for emergency surgery has fallen dramatically in recent years, paralleling improvements in stent technology and pharmacologic therapy, and it now occurs in less than 1% of cases.^{31,63} Cardiac tamponade may develop on occasion because of vessel perforation with the coronary guidewire or with balloon dilation.

The improvements in immediate PCI outcomes and the recognition of improved survival with PCI performed in the setting of acute MI have led to the development of programs performing primary PCI and, more recently, without cardiac surgical backup. Several studies have shown that nonemergency PCI in institutions without on-site surgical backup is safe and effective. Registry data support the safety of elective PCI in community hospitals without the presence of cardiac surgery backup for low-risk patients.^{64,65} The C-PORT study confirmed the safety of primary PCI without surgical backup.⁶⁶ A large, prospective trial conducted in Massachusetts, MASS COMM, randomly assigned 3691 patients presenting to a hospital without on-site cardiac surgery with an indication for nonemergency PCI to either undergo PCI at that hospital or another with surgical backup on-site. There was no significant difference between the rates of composite endpoint of MI, repeat revascularization, stroke, or death at 30 days (9.5% in hospitals without on-site cardiac surgery versus 9.4% in hospitals with on-site cardiac surgery, relative risk 1.00; $P < 0.001$ for noninferiority) or at 1 year (17.3% in hospitals without on-site cardiac surgery versus 17.8% in hospitals with on-site cardiac surgery, relative risk 0.98; $P < 0.001$ for noninferiority).⁶⁷ Current ACC/AHA guidelines for PCI, published prior to the results of CPORT and MASS COMM, recommend primary PCI in hospitals without cardiac surgery backup on-site (class IIa recommendation) provided that the facility can meet certain requirements, including having experienced operators and laboratory staff, rigorous quality assurance, and established protocols for rapid transfer of patients to a facility with cardiac surgery.⁴⁸

It is well known that operator experience and hospital volume play an important role in these cases. Various studies have correlated both limited operator experience (<75 cases/yr) and low hospital volume (<200 cases/yr) with less favorable outcomes for primary PCI.⁶⁸⁻⁷⁰ Particular lesion subsets that would ordinarily be attempted by operators with on-site surgical backup are proscribed when surgical backup is not available. Because of the risk

of catheter injury to the left main artery, culprit stenoses (i.e., occluded 60% or more) that are downstream from a lesion in the LMCA should be avoided. When there is normal flow in the infarct artery, and either the patient has three-vessel disease or the culprit lesion is long or angulated, PCI should be avoided as well. High-grade LMCA disease or hemodynamic instability should prompt rapid transfer to an institution equipped to perform bypass surgery.³²

Emergency CABG is performed mainly for persistent abrupt vessel closure, extensive vessel dissection, unstable LMCA stenosis or injury, uncontrolled vessel perforation, and cardiac tamponade that cannot be controlled. The Society of Thoracic Surgeons reported an operative mortality rate that exceeds 5% for patients requiring emergency bypass surgery within 6 hours of PTCA.^{63,71} Although the frequency of emergency surgery continues to fall, and surgical technique and postprocedure management continue to improve, patient outcomes continue to be significantly worse than for elective surgery. The poor outcomes in this population are not unexpected, because as PCI has improved, the patients who cannot be salvaged and require emergency surgery comprise a population with more unfavorable risk factors and comorbidities. Considerations such as conduit selection, myocardial protection, and the need for coronary artery repair make the surgical procedure technically demanding.

Myocardial Infarction

Although Q-wave MI occurs in less than 1% of patients, the incidence of postprocedure myonecrosis (as measured by elevation of cardiac markers such as creatine phosphokinase [CPK]-MB and troponins [cTn]) can be identified in almost one third of patients and is more common after atherectomy procedures, after PCI performed in thrombus-containing lesions, in the setting of acute coronary syndromes, or for treatment of saphenous vein graft disease.⁷²⁻⁷⁴ Periprocedural MI may result from acute vessel closure, perforation, or most commonly, embolization of thrombus or atheroma. A standard definition of post-PCI MI has been adopted. This definition includes stent thrombosis or elevations of cTn greater than 5 times the 99th percentile upper reference limit occurring within 48 hours of the procedure with normal baseline cTn concentrations and with clinical evidence of ischemia. If the baseline cTn values are elevated and are stable or falling, then a rise of more than 20% is required for the diagnosis of post-PCI MI.⁷⁵ There is controversy as to the importance of asymptomatic elevations in cardiac biomarkers, termed *myocardial injury*, after PCI. Myocardial injury after PCI is associated with increased risk of death in follow-up, but whether these elevations are causally related or simply a marker of an increased burden of comorbidity or generalized atherosclerosis remains a subject of debate.⁷⁶ Many laboratories do not routinely measure cardiac biomarkers after PCI, underestimating the rates of myocardial injury and periprocedural MI after PCI. Other complications of coronary intervention include arrhythmias, stroke caused by spontaneous intracerebral hemorrhage with anticoagulation,

and stroke caused by embolic debris or equipment from catheters, arteries, cardiac chambers, or valves.

Vascular Complications and Hemorrhagic Complications

The use of femoral access, antithrombotic, fibrinolytic, and antiplatelet agents, as well as aggressive anticoagulation and prolonged sheath placement is associated with an increase in vascular complications.⁷⁷ Impaired coagulation and the need for larger-lumen catheters for percutaneous intervention (typically size 5 to 24 Fr) lead to more frequent access-site complications compared with simple diagnostic angiography.

Complications include hematoma (1% to 5%), retroperitoneal hemorrhage, and pseudoaneurysm (1%) formation.⁷⁸ Patients with significant peripheral vascular disease are at higher risk for such complications. Infrequent (<1%) complications include arteriovenous fistula formation, infection of access site or closure device, cholesterol embolization, and vascular occlusion. Femoral access-site complications requiring surgical repair or transfusion occur in 2% to 5% of cases. Closure devices are used frequently to achieve rapid hemostasis and achieve earlier ambulation. These devices have not definitively reduced the rates of vascular complications. Various devices are in use, including those with collagen plugs and percutaneously deployed sutures.

Traditionally, surgery was performed to close pseudoaneurysms greater than 2 cm in diameter because of significant risk of spontaneous rupture. Ultrasound-guided injection of thrombin into the pseudoaneurysm has obviated the need for open surgical repair. Surgical exploration is undertaken for repair of fistulas and arterial lacerations and in cases of arterial occlusion and uncontrolled bleeding leading to hemodynamic compromise. Various studies have demonstrated significant reductions in the rates of vascular complications with radial access for PCI.^{12,13}

Contrast Nephropathy

Contrast-induced nephropathy (CIN) is an important clinical concern. The occurrence of CIN is associated with adverse clinical outcomes, including reductions in survival rates.^{79,80} Although most of these cases are self-limited, a fraction of patients require short-term dialysis and some require permanent dialysis. The risk of permanent dialysis is less than 1% overall. Various risk scores have been developed to predict the occurrence of CIN.⁸¹ Significant predictors include hypotension, intra-aortic balloon pump use, congestive heart failure, chronic kidney disease, diabetes, age older than 75 years, anemia, and volume of contrast. The patients at highest risk have a risk for CIN that exceeds 50%.^{79,80} Additional risk factors include dehydration, advanced age, multiple myeloma, exposure to nephrotoxic drugs, congestive heart failure, and liver disease.

The risk of contrast agent-induced nephropathy can be reduced by hydration with normal saline before and after the procedure. Forced diuresis, calcium antagonists, dopamine, and atrial natriuretic peptide have not been

shown to be beneficial.^{82,83} There is no evidence that *N*-acetylcysteine is of benefit, and thus routine use is not recommended.

Anaphylactoid Reactions

The term *anaphylaxis* is reserved for allergic, IgE-mediated immediate hypersensitivity reactions. *Anaphylactoid* reactions are clinically similar to anaphylaxis but are not IgE mediated. Both anaphylaxis and anaphylactoid reactions can produce immediate, potentially life-threatening systemic reactions because of the massive release of mediators such as histamine from mast cells and basophils.

The incidence of death from contrast media complications in the catheterization laboratory is estimated at 1 in 55,000. Mild cases may be associated with symptoms such as itching, urticaria, flushing, cough, sneezing, wheezing, abdominal cramps, diarrhea, headache, back and chest pain, nausea, vomiting, fever, and chills. More severe reactions lead to dyspnea, a sense of impending doom, and hypotension, infrequently resulting in cardiovascular collapse and death. Depending on the severity of the clinical findings, patients may require treatment with catecholamines, antihistamines, corticosteroids, or intravenous fluids. In patients with prior reactions, pretreatment with corticosteroids and diphenhydramine, and the use of nonionic contrast media have significantly reduced the potential of recurrent reaction.⁸⁴

Restenosis

Despite successful initial luminal enlargement, the Achilles heel of balloon angioplasty has always been restenosis. After the acute arterial injury that is a prerequisite for luminal enlargement, a complex interaction between the vessel and blood elements occurs. Although these processes are often viewed as pathologic, they recapitulate all the elements of wound healing. Immediately after balloon dilation, 20% to 30% of the initial gain may be lost because of vascular recoil. Platelets, neutrophils, and macrophages adhere to the site of injury, resulting in an inflammatory response and secretion of a variety of mitogens. Many of these growth factors, such as platelet-derived growth factor, stimulate a change in smooth muscle cells from a contractile to a proliferative phenotype. Matrix metalloproteinases promote smooth muscle cell migration from the media to the intima. The combination of smooth muscle cell proliferation, neointimal hyperplasia, and elastic recoil (i.e., negative remodeling) is a ubiquitous process that, in most vessels, results in mild to moderate renarrowing; however, in 20% to 50% of patients without stents, it may result in a clinically significant restenosis that may continue for 6 to 12 months.

Although angiographic restenosis may be silent clinically, many patients present with recurrent angina or inducible ischemia during functional testing. It is now recognized that restenosis may not be clinically benign. Approximately 10% of patients with restenosis present with acute MI.⁸⁵ Risk factors for restenosis after PTCA have been well documented (Table 56-2). In large

TABLE 56-2 Risk Factors for Restenosis

Patient Factors	Lesion Factors	Technical Factors
Diabetes	Small vessels	High residual posttreatment stenosis
End-stage renal disease	Left anterior descending location	
Unstable coronary syndrome	Long lesions	
	Prior restenosis	
	Ostial location	
	Bifurcation	

populations, late lumen loss follows a near-Gaussian distribution, with approximately 50% of the initial gain in lumen diameter lost by 6 to 8 months.⁸⁶ The slope of the gain-loss relationship is approximately 0.5, and it is similar across all devices used for PCI. The reduction in restenosis rates observed after BMS placement is entirely explained by the ability of these stents to safely maximize acute gain, thereby allowing greater tolerance for late loss. The DES also decreased neointimal and smooth muscle cell growth, reducing late loss as well, in addition to the greater acute gain seen with the BMS.

ADVANCED TECHNOLOGY IN PERCUTANEOUS CORONARY INTERVENTION

Drug-Eluting Stents

Despite improved outcomes compared with angioplasty alone, BMS restenosis remained a problem in interventional cardiology, with rates ranging from 12% to greater than 50% in certain subgroups with the BMS (see Table 56-2).^{21,87} The advent of the DES introduced local drug delivery from a polymer coating on the stent consisting of anti-inflammatory and antiproliferative medications with a slow controlled release that effectively reduced the incidence of restenosis from 30% to less than 10%.⁸⁸⁻⁹⁰ Restenosis after DES placement is generally treated with repeat PCI, with or without another DES, or with CABG.

DESs were approved for use in 2004 for the treatment of symptomatic ischemic disease in discrete de novo lesions of less than 30 mm long in native coronary arteries with a reference luminal diameter between 2.5 and 3.5 mm for the Cypher (sirolimus-coated stent) and less than 28 mm long in native arteries between 2.5 and 3.75 mm in diameter for the Taxus (paclitaxel-coated stent). As mentioned, with local delivery of polymer coatings eluting paclitaxel, sirolimus, zotarolimus, or everolimus, smooth muscle cell proliferation and neointimal hyperplasia are inhibited, and the incidence of restenosis is drastically reduced. These drugs inhibit neointimal and smooth muscle cell proliferation by either cytostatic or cytotoxic inhibition of the cell cycle. Drugs from the *limus* family also have anti-inflammatory and antimigratory properties. Currently, 60% to 70% of implanted

coronary stents are DESs. Many studies have shown a sustained, long-term benefit of the DESs over the BMSs in reducing target-lesion revascularization.⁹¹⁻⁹⁴

Off-label DES implantation is estimated by the FDA to account for 60% of its current use. Off-label uses include stenting in bifurcation stenoses, ostial or totally occluded lesions, bypass grafts, lesions longer than 30 mm, vessels smaller in diameter than 2.5 mm or larger than 3.5 to 3.75 mm, left main stenosis, or restenosis. The FDA currently concludes that off-label use of a DES may be associated with increased risks compared with a BMS, but studies suggest that these higher risk lesions may actually benefit to a greater degree than on-label uses.^{95,96}

A major concern with the use of a DES is the development of stent thrombosis. Stent thrombosis is classified as early (0 to 30 days), late (31 to 365 days), or very late (more than 365 days), with a level of certainty defined as either probable, possible, or definite. Definite stent thrombosis requires angiographic or autopsy-based evidence of thrombus or occlusion. Probable stent thrombosis is defined as unexplained death within 30 days of PCI, or acute MI in the territory of the stented lesion. Finally, possible stent thrombosis includes all unexplained deaths occurring after 30 days of the index procedure.⁹⁷

Initial pivotal studies showed the incidence of stent thrombosis to be low (0.6% for DES and 0.8% for BMS),^{88,89} with no significant difference in stent thrombosis between the BMS and DES. Studies have shown similar rates of stent thrombosis in the first year when comparing the BMS and DES but then a not statistically significant trend toward increased rates of stent thrombosis with the DES.⁹⁸⁻¹⁰⁰ Because of concern that the premature disruption of DAPT may increase the risk for late in-stent thrombosis, current guidelines recommend uninterrupted DAPT for at least 1 month in those receiving a BMS (minimum of 2 weeks if there is an increased risk of bleeding) and 12 months for DES.¹⁰¹ Various studies have reported similar outcomes with shorter duration DAPT and second-generation DESs, but these studies are not adequately powered to detect small differences in risk of stent thrombosis with premature discontinuation, interruption, or disruption of DAPT with second-generation DESs.¹⁰²

Atherectomy Devices

Atherectomy devices were designed to achieve luminal enlargement by plaque removal rather than dissection and vascular stretching. Directional coronary atherectomy involved a cup-shaped cutter housed in a rigid cylinder in which a window was etched. A balloon was attached to the opposite wall of the cylinder. During balloon inflation, the atheroma was directed into the housing, shaved by the rotating cutter, and compressed into the nose cone for removal. This device was used successfully for treatment of bifurcation, ostial, eccentric, and ulcerated lesions. However, because of technical difficulty and a high incidence of periprocedural MI, directional coronary atherectomy is no longer available.

Rotational atherectomy (RA or PTCRA) incorporates a nickel-plated, brass burr coated with diamond chips on

FIGURE 56-4 ■ Rotational atherectomy catheter. (Courtesy Boston Scientific, Natick, MA.)

its leading edge (Fig. 56-4). The burr is rotated at 140,000 to 200,000 revolutions/min and, using the principle of differential cutting, pulverizes plaque into 5- to 12-micron particles. These particles are cleared by the reticuloendothelial system. Orbital atherectomy includes a centrifugal component of force to the sanding procedure and is approved for use in peripheral and coronary arteries.¹⁰³ Rotational atherectomy and orbital atherectomy are currently used as “enabling devices” prior to PTCA or stenting, to improve vascular compliance in undilatable devices or to debulk heavily calcified plaque.

Thrombectomy and Distal Protection

Treatment of thrombus-containing lesions has been a challenge for the interventional cardiologist. Intraluminal thrombus is associated with a higher risk of periprocedural complications.¹⁰⁴ Current thrombectomy devices use various techniques, including transluminal extraction using a rotating helical auger at the tip of the catheter in conjunction with a luminal suction to remove clots or using an aspiration device, the AngioJet (Boston Scientific, Natick, MA), or simple suction thrombectomy using a variety of hollow-lumen catheters.

The Vein Graft AngioJet Study (VEGAS)-II trial compared intracoronary fibrinolysis with thrombectomy and demonstrated a reduction in 30-day major adverse cardiac events with thrombectomy compared with prolonged infusion of urokinase.¹⁰⁵ Despite effective thrombectomy, distal embolization remains common during treatment of saphenous vein graft disease and in acute coronary syndromes. This has led to the development of devices aimed at reducing distal embolization of plaque and thrombus during high-risk interventions. For example, the PercuSurge GuardWire is a balloon occlusion protection device that uses a coronary guidewire with a hollow hypotube allowing inflation of a distal occlusion balloon. Inflation creates a static column of blood in the vessel, trapping debris liberated during balloon inflation or stent deployment. A sump catheter is then advanced over the wire and used to aspirate the

static column of blood and debris. The Saphenous Vein Graft Angioplasty Free of Emboli Randomized (SAFER) trial demonstrated a 50% reduction in periprocedural MI for patients randomized to the PercuSurge GuardWire compared with conventional systems during intervention on saphenous vein bypass grafts. These devices are approved for use during saphenous vein graft interventions only and have not been proved beneficial in native coronary arteries.¹⁰⁶⁻¹⁰⁸

Second-generation devices are balloon occlusion devices combined with a flush and extraction mechanism and filters mounted at the end of the wire to trap embolized material. The latter have the theoretical advantage over the distal protection balloons that antegrade blood flow can be preserved, limiting ischemic time resulting from occlusion.¹⁰⁹ Randomized comparisons of these devices demonstrated equivalent outcomes.^{110,111}

The routine use of thrombus aspiration in acute MI is controversial. The Thrombus Aspiration during Primary Percutaneous Coronary Intervention Study (TAPAS)¹¹² showed improved myocardial perfusion, ST-segment resolution, and 1-year survival with manual thrombectomy.¹¹³ Based on this study, the European Society of Cardiology (ESC) gave the IIA recommendation that routine thrombus aspiration in STEMI should be considered.¹¹⁴ Subsequently, the Intracoronary Abciximab and Aspiration Thrombectomy in Patients with Large Anterior Myocardial Infarction (INFUSE-AMI) trial investigated the benefits of bolus intracoronary abciximab and manual aspiration thrombectomy in STEMI patients with proximal or mid LAD artery occlusions. Infarct size at 30 days, as measured by cardiac magnetic resonance imaging (MRI), was significantly reduced with intracoronary abciximab but not with aspiration thrombectomy.¹¹⁵ A meta-analysis (18 trials, $N = 3936$) evaluating thrombectomy compared with conventional PCI concluded that the rates of major adverse cardiac events and all-cause mortality were decreased with aspiration thrombectomy (RR = 0.71; 95% CI 0.51-0.99; $P = 0.049$).¹¹⁶ These results were mainly driven by TAPAS, the largest study at the time.

The Thrombus Aspiration during ST-Segment Elevation Myocardial Infarction (TASTE) trial randomized the largest number ($N = 7244$) of patients with STEMI comparing routine thrombus aspiration before PCI to PCI alone. Despite being appropriately powered, this study showed no clinically relevant difference in 30-day mortality (2.8% vs. 3.0%; $P = 0.07$).¹¹⁷ Longer term data from the TASTE trial are pending.

The use of mechanical thrombectomy in STEMI appears to be harmful. In the AngioJet Rheolytic Thrombectomy in Patients Undergoing Primary Angioplasty for Acute Myocardial Infarction (AiMI) trial, a total of 480 patients were randomized to rheolytic thrombectomy with AngioJet or conventional primary angioplasty. The primary endpoint was infarct size estimated by technetium 99m sestamibi. This trial showed a larger infarct size and higher mortality in patients treated with mechanical thrombectomy compared with those treated with conventional primary angioplasty, an effect also observed in meta-analysis.¹¹⁶ Given the lack of benefit seen in randomized trials, the effectiveness of routine thrombus

aspiration in acute MI remains uncertain and should be reserved for selected cases with high thrombus burden and where a large amount of myocardium is at risk.

Intravascular Ultrasound

Intravascular ultrasound (IVUS) is an invasive tomographic imaging modality that provides visualization not only of the vessel lumen but also of the vessel itself, and therefore it can provide information regarding vessel cross-sectional area, plaque characteristics, and stent expansion, and it is helpful when angiography is inconclusive or inadequate. Newer IVUS devices allow in vivo histopathologic characterization. Techniques to identify vulnerable plaques using IVUS are currently in development.

Catheter-Based Therapy after Bypass

In the first year after bypass surgery, approximately 8% of patients require repeat revascularization because of a recurrence of ischemia.¹¹⁸ Over time, the number of patients who develop recurrences of symptoms increases substantially. The recurrences result from saphenous vein graft attrition in most cases, although progression of native vessel disease also contributes to recurrent ischemia. Approximately 7% of grafts fail in the first week, and another 15% to 20% in the first year. Thereafter, 1% to 2% each year fail during the first 5 to 6 years, and this increases to 3% to 5% each year in years 6 to 10 postoperatively.¹¹⁹ At 10 years postoperatively, approximately half of all saphenous vein graft conduits are occluded, and only half of the remaining patent grafts are free of significant disease.³² Arterial conduit grafts, especially the left internal mammary, are relatively resistant to atherosclerosis. Because of the increase in morbidity associated with repeat CABG,¹²⁰ PCI, if technically possible, is the preferred strategy. Graft failure in the first month of surgery is usually the result of thrombosis resulting from nonlaminar flow,¹²¹ whereas perianastomotic stenosis is usually the culprit 1 to 12 months after surgery and histologically resembles restenosis after PCI. The latter responds well to balloon dilation.

Ischemia occurring more than 1 year after surgery may result from progression of atherosclerotic disease in the native coronary vessels or accelerated atherosclerosis in bypass grafts.¹²² As the disease in these grafts progresses, the plaques become diffuse and are often degenerated, bulky, and thrombotic. Vein graft atherosclerotic lesions often lack thick fibrous caps. PCI on these vessels is associated with substantial risk of distal embolization and periprocedural MI.¹²³ This risk may be reduced by the use of thrombectomy devices and embolic protection devices.^{105,106} Even if PCI of a saphenous vein graft is performed successfully without adverse events, recurrent ischemic events are common as a result of restenosis and rapidly progressive disease in the saphenous vein graft and native vessels.¹²² Such patients, particularly those without a patent arterial conduit to the LAD artery, should receive serious consideration for repeat surgical revascularization. A DES in vein grafts has been shown to reduce restenosis compared with a BMS, although

the Reduction of Restenosis in Saphenous Vein Grafts with Cypher Sirolimus-Eluting Stent (RRISC) trial reported an excess of late mortality with DES.¹²⁴ Consensus guidelines have been published for PCI after CABG (Box 56-2).¹⁰¹

Hybrid Coronary Revascularization

Although bypass surgery has longer patency rates using left internal mammary artery grafts and decreased target lesion revascularization, the inherent limitations of vein graft conduits and improved outcomes with DES may require a multidisciplinary approach to revascularization. Therefore, these “hybrid revascularizations” use both stenting and internal mammary grafting through a mini-thoracotomy or minimally invasive direct coronary artery bypass (MIDCAB) grafting. In one study, the incidence of adverse cardiovascular events was decreased in the hybrid arm using DES compared with off-pump bypass surgery, both in the early postoperative period and at 1 year.¹²⁵ This approach requires further investigation.

BOX 56-2

Recommendations for Percutaneous Coronary Intervention (PCI) in Patients with Prior Coronary Artery Bypass Graft (CABG) Surgery

CLASS I: CONDITIONS FOR WHICH THERE IS EVIDENCE FOR AND/OR GENERAL AGREEMENT THAT THE PROCEDURE OR TREATMENT IS USEFUL AND EFFECTIVE

- Patients with early ischemia (usually within 30 days) after bypass surgery.
- It is recommended that distal embolic protection devices be used when technically feasible in patients undergoing PCI to saphenous vein grafts.

CLASS IIA: CONDITIONS WHERE THERE IS CONFLICTING EVIDENCE, BUT WEIGHT OF EVIDENCE/OPINION IS IN FAVOR OF USEFULNESS/EFFICACY

- Patients with ischemia occurring 1 to 3 years postoperatively and preserved left ventricular function with discrete lesions in graft conduits.
- Disabling angina secondary to new disease in a native coronary circulation. (If angina is not typical, the objective evidence of ischemia should be obtained.)
- Patients with diseased vein grafts more than 3 years after bypass surgery.
- PCI is reasonable and technically feasible in patients with a patent left internal mammary artery graft who have clinically significant obstructions in other vessels.

CLASS III: CONDITIONS FOR WHICH THERE IS EVIDENCE AND/OR GENERAL AGREEMENT THAT THE PROCEDURE/TREATMENT IS NOT USEFUL/EFFECTIVE AND, IN SOME CASES, MAY BE HARMFUL

- PCI to chronic total vein graft occlusions.
- Patients with multivessel disease, failure of or multiple saphenous vein grafts, and impaired left ventricular function unless repeat CABG poses excessive risk because of severe comorbid conditions.

PHARMACOLOGY

Surgical Considerations for Anticoagulation

An important consideration is the timing of surgery if antiplatelet medications have been administered. Low-dose aspirin should be continued. The incidence of increased bleeding is associated with the use of either thienopyridines or GP IIb/IIIa inhibitors when urgent CABG is performed. However, no increase in operative bleeding was seen when GP IIb/IIIa inhibitors were discontinued at least 2 hours before surgery.¹²⁶⁻¹²⁸ For clopidogrel and ticagrelor, it is advisable to delay cardiac surgery for 5 days and for 7 days with prasugrel.^{129,130} Platelet transfusion may reverse the effect of the GP IIb/IIIa receptor antagonist, abciximab, and reduce the incidence of bleeding but is of no usefulness with eptifibatide and tirofiban.^{131,132} Surgery within 12 hours of fibrinolytic therapy for patients with acute MI is associated with increased bleeding and transfusion and with a greater incidence of reoperation for perioperative bleeding.¹³³ Unfortunately, the clinical condition of the patient often supervenes and surgery must occur prior to the completion of a washout period. Although bleeding, chest tube output, and transfusion rates are increased in such circumstances, adverse outcomes in this population are likely related more to the underlying condition of the patient requiring urgent cardiac surgery than to the antiplatelet medication.^{132,134} A strategy of preoperative assessment of platelet function after withdrawal of clopidogrel shows promise in guiding the optimal timing of CABG.¹³⁵

Current guidelines suggest that DAPT should be administered for at least 1 month after BMS placement and for 1 year after DES placement (class I).^{32,35,101} Some data suggest that the duration of DAPT can be shortened with newer generation stents, but these data require further confirmation.¹⁰² Whether DAPT is necessary after 1 year remains controversial and is the subject of ongoing investigation.

NONCORONARY INTERVENTIONAL CARDIAC PROCEDURES

Improvements in catheters, guidewires, balloons, stents, and other technologies have facilitated the use of catheter-based therapies and have allowed interventional cardiologists to treat noncoronary cardiac problems such as valvular, congenital, and other structural heart diseases that previously were the purview of surgical therapy only. In addition, the development of percutaneous assist devices allows the interventional cardiologist to treat the highest risk patients with an added degree of safety.

Balloon Mitral Valvuloplasty

Inoue and coworkers in 1984 and Lock and colleagues in 1985 introduced percutaneous mitral balloon valvotomy (PMBV) for the treatment of selected patients with mitral

stenosis.^{136,137} A single deflated balloon or a double balloon is advanced from the venous access to the right atrium. Using a trans-septal approach, the balloon is advanced across the interatrial septum to the left atrium and then across the stenotic mitral valve. The balloon is inflated and rapidly deflated, fracturing calcifications of the leaflet tissue and separating fused commissures. Typically, the valve area increases from a critically stenotic value of less than 1.0 cm² to approximately 2.0 cm², a change associated in 80% to 95% of patients with a rapid reduction in left atrial pressure that is sufficient to produce substantial hemodynamic improvements, including a 50% to 60% decrease in the transmitral pressure gradient, a reduction in pulmonary artery pressure, and an increase in cardiac output.

Patients are selected for PMBV on the basis of echocardiographic and clinical criteria. PMBV is a reasonable option for patients who are candidates for surgical commissurotomy. The salutary long-term results, lower costs, and the avoidance of thoracotomy make this procedure the treatment of choice in young patients with pliable, noncalcified mitral valves and no left atrial thrombus.¹³⁸ In addition, percutaneous valvotomy can be considered a palliative procedure in patients who have severe valve deformities and are poor surgical candidates. Mitral valve repair or replacement is usually preferred in symptomatic patients with severe subvalvular or calcific disease or when left atrial thrombus or significant mitral regurgitation precludes safe balloon valvotomy. Closed commissurotomy is still performed in some developing nations where cost and lack of balloon catheters are continuing problems.

The ACC/AHA task force published recommendations for PMBV in 2006¹³⁹ and recommended consideration of PMBV for patients who have exercise intolerance, severe pulmonary hypertension, no left atrial thrombus, a calculated effective mitral valve area of 1.5 cm² or less with trace or mild mitral regurgitation, and appropriate mitral anatomy as determined by echocardiography.

Echocardiography is an essential screening procedure in patients being considered for PMBV.¹³⁸ The extent of valvular and subvalvular deformity can be evaluated, and the likelihood of a successful result can be assessed. This can be accomplished by applying the Wilkins score, which scores from 0 to 4 for each of four factors: (1) the degree of leaflet rigidity, (2) the severity of leaflet thickening, (3) the amount of leaflet calcification, and (4) the extent of subvalvular thickening and calcification. The maximum score is 16; higher scores indicate more severe anatomic disease and a lower likelihood of a successful PMBV.¹⁴⁰

The National Heart, Lung, and Blood Institute's Balloon Valvuloplasty Registry evaluated 736 patients older than 18 and treated with PMBV who were followed for 4 years. The actuarial survival rates at 1, 2, 3, and 4 years were 93%, 90%, 87%, and 84%, respectively. The event-free survival rates (freedom from death, mitral valve surgery, or repeat balloon valvotomy) at 1, 2, 3, and 4 years were 80%, 71%, 66%, and 60%, respectively.¹⁴¹ The clinical and hemodynamic results of PMBV have been compared with the different forms of surgical correction: closed surgical valvotomy and open and closed

surgical commissurotomy. The outcome after PMBV was as good as or better than after surgery for patients who are candidates for valvotomy.^{142,143} Long-term outcomes are actually improved in PMBV as compared with closed commissurotomy.^{26,142}

Complications of PMBV include severe mitral regurgitation in 2% to 10% of patients, mitral valve restenosis, or formation of an atrial septal defect. After PMBV, up to 21% of patients develop recurrent heart failure as a result of mitral valve restenosis. Although most of these patients undergo mitral valve replacement, repeat balloon valvuloplasty is an alternative approach, especially in patients who are not good surgical candidates.¹⁴⁴ In addition, mitral valve restenosis after previous commissurotomy can be treated with PMBV. The immediate hemodynamic results and the long-term hemodynamics appear to be identical to those seen with balloon valvotomy in unoperated mitral stenosis.¹⁴⁵

Percutaneous Mitral Valve Repair and Replacement

Percutaneous mitral valve replacement has been performed in both native¹⁴⁶ and bioprosthetic mitral valves.¹⁴⁷ Approximating an Alfieri stitch, the Evalve MitraClip system (Fig. 56-5) is approved for percutaneous mitral valve repair in those with moderate-severe or severe mitral regurgitation caused by valve degeneration. The Endovascular Valve Edge-to-Edge Repair Study (EVEREST) evaluated the trans-septal approach for applying a clip device (Evalve, Inc., Menlo Park, CA) to the mitral valve. The trial reported an 85% freedom from adverse events rate at 30 days and a freedom from valve surgery rate of 82% at 6 months.¹⁴⁸ The pivotal randomized controlled clinical trial, EVEREST II, compared the percutaneous MitraClip ($n = 184$) to mitral valve surgery ($n = 95$). At 4 years, the rate of the composite endpoint of freedom from death, surgery, or 3+ or 4+ MR in the intention-to-treat population was 39.8% versus 53.4% in

the percutaneous repair group and surgical groups, respectively ($P = 0.070$). Surgery for mitral valve dysfunction, however, occurred in 20.4% versus 2.2% ($P < 0.001$) at 1 year and 24.8% versus 5.5% ($P < 0.001$) at 4 years.¹⁴⁹ The EVEREST II trial also incorporated a nonrandomized high-risk arm evaluating subjects at elevated surgical risk. In this arm, the MitraClip procedure was attempted in 78 subjects. The observed mortality rate in this group was 7.7% at 30 days, comparing favorably to a mean predicted mortality by Society of Thoracic Surgeons (STS) score of 18.2%.¹⁵⁰ Numerous devices are in development for percutaneous treatment of mitral regurgitation. Given the complexity of the mitral valve apparatus, it is unlikely that one device will address the multitude of pathologies afflicting the mitral valve.

Balloon Aortic Valvuloplasty

Percutaneous balloon aortic valvuloplasty (BAV) can also be performed for aortic stenosis. Typically, one or more balloons are advanced across a stenotic valve in a retrograde manner and inflated to dilate the valve.¹⁵¹ This procedure has an important role in treating adolescents and young adults with congenital aortic stenosis. In patients with bicuspid or calcific valvular aortic stenosis, the mechanism of dilation is through fracture of calcific deposits in the valve leaflets as well as stretching of the annulus with separation of the calcified or fused commissures.¹⁵² Although there is often immediate and significant reduction in the transvalvular pressure gradient, the postvalvotomy valve area rarely exceeds 1.0 cm². Despite this modest change in valve area, symptomatic improvement is usually seen.¹⁵³

The role for BAV is limited by complications such as stroke ($\approx 2\%$), coronary occlusion ($\approx 0.5\%$), severe aortic regurgitation ($\approx 1\%$), and vascular complications ($>7\%$), as well as poor clinical durability.¹⁵³ Restenosis and clinical deterioration occur within 6 to 12 months in most patients, and, in contrast to the results after surgical aortic valve replacement, there is no impact on long-term survival. Thus, BAV should not be considered a substitute for aortic valve replacement.¹⁵⁴⁻¹⁵⁶ BAV can be performed in some cases as a bridge to surgical or transcatheter aortic valve replacement in patients who are at high risk for surgical aortic valve replacement or in asymptomatic patients who require urgent noncardiac surgery. BAV may also be performed for palliation of congestive heart failure in patients with serious comorbidities and limited life expectancy.¹⁵⁶ An additional role for BAV is in cases where, despite provocative testing, it remains unclear whether cardiac performance is limited by aortic stenosis or profound ventricular dysfunction. In such cases, valvuloplasty can be performed to determine whether there is clinical improvement so that a decision can be made whether surgical or transcatheter aortic valve replacement should subsequently be performed.¹⁵⁷

Ethanol Septal Ablation for Hypertrophic Obstructive Cardiomyopathy

Nonsurgical septal reduction therapy, also called alcohol septal ablation, is a procedure whereby percutaneous

FIGURE 56-5 ■ MitraClip percutaneous mitral valve repair catheter. (Courtesy Abbott Vascular, Inc., Abbott Park, IL.)

obliteration of the first or second septal perforating coronary arteries is performed using absolute alcohol, which causes an iatrogenic septal infarct to reduce left ventricular outflow tract obstruction and thereby improve symptoms. Alcohol is injected through the lumen of an inflated angioplasty balloon into the septal branch, causing the infarction. Transient heart block is common, necessitating placement of a prophylactic pacing wire.¹⁵⁸

Symptomatic patients with moderate to severe heart failure symptoms, an interventricular septal thickness of 18 mm or greater, a left ventricular outflow tract gradient at rest of at least 30 mm Hg, or an intraventricular gradient during provocation are potential candidates for this procedure.¹⁵⁹

Septal reduction therapy has been shown to produce impressive reductions in outflow tract gradient and in symptoms. Significant reductions in pulmonary pressures, outflow tract gradient, and left ventricular hypertrophy and mass have been demonstrated.^{160,161} Immediate hemodynamic results are comparable to those found with surgical myotomy or myectomy.¹⁶²⁻¹⁶⁴ The most common complication of the procedure is the development of complete heart block, requiring a permanent pacemaker in approximately 7% to 14% of patients¹⁶⁵⁻¹⁶⁷ up to 5 days after the procedure, right bundle branch block in greater than 40%, and primary atrioventricular conduction abnormality in greater than 50%.¹⁵⁸ The risk of complete heart block is increased with septal ablation in those with a baseline left bundle branch block, because ablation usually targets the basal septum, which lies closer to the right bundle. Right bundle branch block is a risk factor for heart block with septal myectomy.¹⁵⁸

Other complications include the development of coronary dissection, ventricular arrhythmia, or unwanted, extensive MI. Reported results at 1 year follow-up continue to show benefit, especially in those older than 65 years,^{168,169} and long-term efficacy data are currently being collected. The procedural complication rate for septal ablation is higher than for surgical myectomy, although the survival rates are similar.^{166,167}

Closure of Patent Foramen Ovale and Atrial Septal Defect

Patent foramen ovale (PFO), present in roughly 25% of adults, is a persistent flaplike opening between the remnants of the atrial septum primum and the secundum. It can be demonstrated in almost 50% of patients younger than 55 years with cryptogenic stroke.^{170,171} The presumed cause of stroke in these cases is paradoxical embolism, whereby venous thrombus is allowed to access the systemic circulation through the PFO during physiologic conditions when right atrial pressure exceeds left atrial pressure. Medical therapy with either warfarin or antiplatelet agents is the current standard of care for cryptogenic stroke in patients with PFO, but despite its use, the risk of recurrent stroke remains high. Patients with PFO and paradoxical embolism have an approximately 3.5% yearly risk of recurrent cerebrovascular events.¹⁷² Surgical closure has been effective in preventing recurrent stroke.¹⁷³

Because of the bleeding risks associated with chronic anticoagulant use, the costs of drugs and monitoring, and

the desire of physicians and patients to avoid prolonged recovery and open-heart surgery, percutaneous closure can be offered as a less invasive option for stroke prevention in these patients. Percutaneous PFO closure has been used in thousands of patients using a variety of occlusion devices. Procedural outcomes are excellent at selected high-volume centers, with an incidence rate of 0.79 events per 100 person-years and freedom from recurrent events of 91.6% at 10 years.¹⁷⁴⁻¹⁷⁷ Nevertheless, the effectiveness of percutaneous PFO closure compared with surgical closure or medical management for preventing recurrent embolic events is not established. Current evidence derived from a pooled analysis of intention-to-treat data from three randomized controlled trials (CLOSURE I, PC, and RESPECT) indicates that device closure of a PFO does not offer significant benefit over medical therapy alone for the prevention of recurrent stroke (risk ratio 0.66; 95% CI 0.37-1.19).¹⁷⁸⁻¹⁸⁰ These trials have some limitations including short duration of follow-up, enrollment bias, unequal dropout rates, and low event rates.

Data from 2303 patients were evaluated in a meta-analysis of the three randomized trials. The stroke HR for PFO closure versus medical therapy was 0.67 (95% CI 0.44-1.00, I² = 0%). Pooling trials using the Amplatzer PFO occluder (Fig. 56-6) device resulted in a significant reduction of stroke (HR 0.54; 95% CI 0.29-1.01, I² = 0%).¹⁷⁸⁻¹⁸¹ There is also a high prevalence of PFO in patients with classic migraine headaches, but to date no clear data support its use in this population.¹⁸²

Although PFO represents a potential communication between the left and right atria, atrial septal defects (ASDs) are congenital abnormalities characterized by a structural deficiency that leads to continuous, free communication between the atria. The defect is often asymptomatic until adulthood, but complications of an undetected lesion include irreversible pulmonary hypertension, right ventricular failure, atrial arrhythmias,

FIGURE 56-6 ■ Amplatzer septal occlusion devices used for percutaneous closure. (Courtesy AGA Medical Corporation, Plymouth, MN.)

paradoxical embolization, and cerebral abscess. These defects are generally repaired when the pulmonary-to-systemic flow ratio is 1.5 or greater, or in cases where the defect leads to symptoms, embolism, or right ventricular dysfunction. Scuba divers with neurologic compression sickness and ASD should be considered for closure.

Those with ostium primum defects, sinus venosus defects, or defects with less than 4 mm of surrounding tissue or a stretched diameter of greater than 38 mm are better served by surgical rather than percutaneous closure. Percutaneous closure is usually performed using septal occlusion devices similar to those used for PFO closure. Adjunctive transesophageal echocardiographic or intracardiac echocardiography is often used to assist in sizing and placement. One multicenter nonrandomized study compared 154 patients who underwent surgical closure and 442 who had closure with an Amplatzer septal occluder device. The methods had equal success rates, but percutaneous closure was associated with fewer complications (7.2% vs. 24.0%; $P < 0.0001$) and a shorter duration of hospitalization (1 vs. 3 days).¹⁸³

Endovascular ventricular septal defect (VSD) closure is associated with a postprocedural complete closure rate of 47%, which rose to 69.6% at 6 months and then 92.3% at 12 months using an Amplatzer VSD closure device in muscular VSDs.¹⁸⁴ Amplatzer VSD closure devices are also being studied for membranous VSDs, with complete closure demonstrated in phase I trials in 20 of 32 patients at 24 hours and 27 of 28 patients at 6-month follow-up.¹⁸⁵ Significant periprocedural complications (roughly 11.5%) have included device embolization and vascular and arrhythmogenic complications.¹⁸⁶ These investigational devices hold a promising future in the endovascular repair of congenital or post-MI ventricular defects.

Vascular plugs have been used for closure of paravalvular leaks (PVLs) in both surgical and transcatheter valves. Prosthetic valve replacement surgery is performed in approximately 210,000 patients annually worldwide. At least 3%, and possibly as many as 12.5%, of these valves will eventually demonstrate a clinically important PVL. Large series of percutaneous PVL closure have been published, with encouraging results with respect to both procedural success and clinical outcomes. Procedural success for percutaneous closure of paravalvular aortic leaks is approximately 90% in the different series, with low complication rates. Mitral leaks have been approached by transfemoral and transapical access; the reported success of this procedure ranges from 75% to more than 90% in different reports.¹⁸⁷

Percutaneous Circulatory Assist Devices

Circulatory assist devices are used in the catheterization laboratory to support high-risk PCI procedures and support patients in cardiogenic shock as a bridge to recovery or further therapy such as surgical ventricular assist devices or cardiac transplantation. These devices have been shown to improve cardiac hemodynamics, but identifying a relationship between use of these devices and improved survival has been challenging. The challenge stems, in part, from the inherent difficulty in identifying

and studying a population in whom the risk is high enough to warrant this therapy but in whom illness is not so severe that such therapy is futile regardless of hemodynamic improvement. As such, these devices are not used routinely and are reserved for selected cases such as patients who are in extremis but deemed salvageable.

The intra-aortic balloon pump (IABP) uses the principle of counterpulsation to increase diastolic blood flow to coronary arteries and to mechanically reduce the afterload on the heart during systole. This method was first described in 1952 in animals by Adrian and Arthur Kantrowitz.¹⁸⁸ The device consists of a double-lumen catheter from 7 to 9.5 Fr with a 25- to 50-mL balloon at its distal end. The inner lumen monitors arterial blood pressure, and the outer lumen allows the transfer of helium gas into the balloon. It is used in patients with cardiogenic shock or with mechanical complications of MI such as acute mitral regurgitation or VSD, or as a bridge for high-risk patients before bypass surgery.¹⁸⁹ The IABP is contraindicated in those with aortic regurgitation and significant peripheral vascular disease. A randomized trial of IABP versus standard care for anterior MI without cardiogenic shock demonstrated no survival advantage or reduction in infarct size and increased vascular complications.¹⁹⁰ In the IABP-SHOCK II study, patients with shock complicating MI who were to undergo PCI had no survival advantage (39.7% vs. 41.3%; $P = 0.69$; relative risk with IABP 0.96, 95% CI [0.79-1.17]) with the IABP.¹⁹¹ Despite these data arguing against routine use in these populations, it is clear that this technology can be lifesaving for selected patients.

Left ventricular assist devices maintain partial or total circulatory support in cases of profound myocardial dysfunction or temporarily during high-risk PCI. The Impella 2.5 device (Abiomed, Danvers, MA) is a catheter-mounted microaxial blood pump. It features a motorized pump that is inserted into the left ventricle through the aortic valve by means of the femoral artery. The pump produces a mean flow of 2.5 liter/min and mechanically “unloads” the left ventricle (Fig. 56-7) by aspirating

FIGURE 56-7 ■ The Impella 2.5 device used for percutaneous cardiac support. A flow of up to 2.5 liter/min can be provided by this device. (Courtesy Abiomed Corporation, Danvers, MA.)

FIGURE 56-8 ■ The TandemHeart percutaneous ventricular assist device. The catheter is advanced through the femoral vein and across the interatrial septum into the left atrium. Blood is removed, and a pump returns blood to the patient's systemic circulation through an arterial cannula. A flow of up to 5 liter/min can be provided. (Courtesy Cardiac Assist, Inc., Pittsburgh, PA.)

blood from the left ventricle and then expelling it into the aorta by means of a rotor-driven pump. Current FDA approval allows the Impella device to be used for 6 hours, but studies have shown it to be safe for up to 7 days in humans. Randomized trials comparing Impella and IABP support for high-risk PCI^{192,193} have shown that at 90 days, the rates of composite endpoints were lower in the Impella group compared with the IABP group (rate of major adverse cardiac and cerebral events, 22% vs. 31%, $P = 0.034$, respectively). For primary PCI performed in patients with refractory cardiogenic shock,¹⁹⁴ significantly improved hemodynamics and a suggestion of improved outcomes with initiation of support prior to PCI has been noted in a registry. A larger Impella device that provides

up to 5 liter/min can be implanted via a surgical approach, and the Impella CP device provides greater than 2.5 liter/min support via a percutaneous approach.

The TandemHeart (Cardiac Assist, Pittsburgh, PA) is a left atrial-to-femoral artery bypass system comprising a trans-septal cannula, arterial cannulae, and a centrifugal blood pump (Fig. 56-8). The pump can deliver flow rates up to 5.0 liter/min at a maximum speed of 7500 rpm. In this case, blood is taken from the left atrium, significantly reducing left ventricular preload, alleviating pulmonary edema, and returned to the aorta retrogradely via the femoral artery and to augment cardiac output. In a randomized comparison between the TandemHeart and IABP in patients with cardiogenic shock, the improved cardiac index afforded by the TandemHeart device resulted in a more rapid decrease in serum lactate and improved renal function.¹⁹⁵ This pump has been used with a right atrial to femoral arterial cannulation and an in-line membrane oxygenator to provide both circulatory and oxygenation support. In this case, left ventricular preload is not reduced and afterload is increased, but an advantage is the circuit can be initiated within minutes. Additionally, a right atrial to pulmonary artery circuit has been used for right ventricular support.

CONCLUSION

ACUTE CORONARY SYNDROME

Definition

Acute coronary syndrome (ACS) refers to a constellation of clinical symptoms (usually including some type of chest discomfort) that is compatible with acute myocardial ischemia.¹ Patients with suspected ACS may eventually prove to have a diagnosis other than ischemia. However, true ACS can be classified into the following clinical subsets:

1. ST-segment elevation myocardial infarction (STEMI).
2. Non-ST-segment elevation ACS (NSTEMI). This can be subcategorized as either unstable angina (UA) or non-ST-segment elevation MI (NSTEMI).

Typically UA presents in one of three ways: prolonged angina at rest (usually >20 minutes); new-onset Canadian Cardiovascular Society (CCS) class III angina; or increasing frequency, severity, and class of angina (increased ≥ 1 class from baseline and reaching CCS class III or higher).² Frequently, UA is accompanied by ischemic electrocardiographic changes. NSTEMI is distinguished from UA by elevation of cardiac biomarkers suggestive of myocardial necrosis.

Epidemiology

Of 1,141,000 hospitalizations for ACS in 2010, approximately 70% were classified as myocardial infarction (MI) and 30% as UA.³ In the National Registry of Myocardial Infarction 4 (NRMI-4) and the Global Registry of Acute Coronary Events (GRACE), 29% of all MI patients and

FIGURE 57-1 ■ Optical coherence tomographic images of disrupted plaque at culprit site in acute coronary syndrome. **A**, The thickness of ruptured fibrous cap is 40 μm , and crater formation is identified within lipid plaque in a ruptured plaque. **B**, Ulceration (yellow arrows) of thick fibrous cap is observed with white thrombus (green arrows) in plaque erosion. (From Akasaka T, Kubo T, Mizukoshi M, et al: Pathophysiology of acute coronary syndrome assessed by optical coherence tomography. *J Cardiol* 56:8–14, 2010.)

27% of ACS patients were diagnosed with STEMI, respectively.^{4,5} Aggressive treatment of patients with NSTEMI and STEMI has yielded significant reductions in recurrent MI, cardiogenic shock, and in-hospital mortality. Nevertheless, up to 25% of opportunities to provide American College of Cardiology/American Heart Association (ACC/AHA) guideline-recommended care are still missed, and these omissions correlate with increased in-hospital mortality.⁴ The recommendations for treatment of NSTEMI/ACS in this chapter are therefore based on the 2007 American College of Cardiology Foundation (ACCF)/AHA guidelines for the management of patients with UA/NSTEMI with incorporation of the 2012 focused update.¹ Recommended management of STEMI is based on the recently updated 2013 ACCF/AHA guidelines.⁶

Pathophysiology

Plaque Rupture/Erosion

Advanced atherosclerotic coronary lesions are characterized by a lipid-rich necrotic core encapsulated by a fibrous cap composed of smooth muscle cells, collagen, and elastin. Mechanisms such as digestion of the fibrous cap by matrix metalloproteinases, loss of smooth muscle cells through apoptosis, and plaque hemorrhage can create a thin-cap fibroatheroma (TCFA) or “vulnerable plaque.”⁷ Rupture of a TCFA is the most common precipitant of ACS (Fig. 57-1). Another mechanism of ACS involves superficial erosion of less advanced lesions, typically rich in proteoglycan matrix and smooth muscle cells. Both plaque rupture and erosion precipitate intracoronary thrombus formation via exposure of highly thrombogenic subendothelial collagen, necrotic material, and the lipid pool to von Willebrand factor (vWF) and platelets. In an autopsy study, plaque rupture or erosion with thrombus was noted in all patients who died of sudden cardiac death caused by ACS.⁸ Patients who had evidence of ruptured fibrous caps were older, were more often male, and had

greater luminal area stenosis, calcification, and macrophage and T cell infiltration than patients who had plaque erosion.

Central Role of Platelets

Platelets are central to the pathogenesis of ACS. Platelets adhere to collagen and soluble vWF immobilized by exposed subendothelial collagen. This is followed by the release of adenosine diphosphate (ADP), thromboxane A₂, and serotonin from platelet granules. Along with thrombin, collagen, and epinephrine, these factors promote platelet recruitment and “activation.” Activation involves platelet shape change, expression of pro-inflammatory ligands, and conversion of the glycoprotein (GP) IIb/IIIa receptor to its active form.⁸ Platelets then aggregate, by cross-linking with each other, via fibrinogen, which attaches to the active GP IIb/IIIa receptor. Thrombin, generated by tissue factor released from eroded plaque, results in formation of fibrin. Cross-linked platelets combine with fibrin to form an occlusive or subocclusive thrombus (Fig. 57-2). Platelet activators amplify the process by promoting each other’s release and induction of procoagulant activity.

Role of Inflammation

ACS is characterized by an acute inflammatory state. Platelets induce inflammation in endothelial cells, and inflamed intact or damaged endothelium is able to bind to platelets. Activated platelets secrete CD40 ligand, which binds to CD40 on endothelial cells. This process induces release of factors that stimulate expression of adhesion molecules, such as ICAM-1 on endothelial cells and P-selectin on platelets.⁹ The resultant platelet-monocyte-neutrophil interactions stimulate release of prothrombotic and proinflammatory factors, leukocyte attachment to the endothelium, and release of matrix metalloproteinase, leading to basement membrane degradation, thereby favoring plaque rupture.¹⁰

FIGURE 57-2 ■ Platelet plug formation. Vascular injury results in the exposure of collagen and von Willebrand factor (vWF) in the vessel wall. Circulating platelets adhere and form a monolayer of activated platelets on the collagen matrix, which drives the release of adenosine diphosphate (ADP) and thromboxane (Tx) A₂ from the adherent platelets. Secretion of ADP and TxA₂ promotes changes in platelet shape and amplification of platelet activation. Thrombin, generated by locally produced tissue factor (TF), is the most potent platelet activator. In the perpetuation phase, platelet contacts promote growth and stabilization of the platelet plug. GP, Glycoprotein. (From Jennings LK: Mechanisms of platelet activation: need for new strategies to protect against platelet-mediated atherothrombosis. *Thromb Haemost* 102:248–257, 2009.)

Diagnosis

Clinical Manifestations

The most common presentation of ACS is some type of prolonged chest discomfort. One third to one half of MIs may be clinically silent. Women, older patients, patients with diabetics, and those with a history of heart failure are more likely to present without chest discomfort. The lack of typical symptoms may lead to delays in presentation to the hospital, establishment of a diagnosis, and institution of medical therapy and revascularization. Symptoms other than chest pain that may reflect ACS include unexplained dyspnea, nausea or indigestion, arrhythmias, syncope, back or arm pain, and fatigue. Unexplained dyspnea, without angina, is associated with more than twice the risk of death compared with patients with typical angina.¹¹

Electrocardiography

The earliest manifestations of myocardial ischemia on an electrocardiogram (ECG) are typically ST-segment and T-wave changes. New horizontal or down-sloping ST depression greater than 0.5 mm or T-wave inversion greater than 1 mm in two contiguous leads is suggestive of ischemia in patients with symptoms compatible with NSTEMI/ACS.¹² ST-segment and T-wave changes can also be caused by left ventricular hypertrophy, pericarditis, early repolarization, or electrolyte imbalance. Therefore, comparison with available prior tracings and interpretation in the context of the clinical symptoms are recommended. The hallmark of STEMI is ST elevation in anatomically contiguous leads or a new left bundle branch block (LBBB). Of note, J point elevation of up to 2.5 mm can be noted in healthy men younger than 40 years.

Cardiac Biomarkers

The preferred biomarkers for diagnosis of MI are cardiac troponin (cTN) T or I. These proteins are part of the myocardial contractile apparatus and are highly sensitive and specific for the diagnosis of myocardial necrosis. However, it is now widely recognized that cTN elevation can occur in the setting of non-ischemic causes of myocardial necrosis or injury such as congestive heart failure (CHF), sepsis, renal failure, pulmonary embolism, or myocarditis. Another commonly used biomarker is CPK-MB, but this is much less specific because of its presence in skeletal muscle and other organs. It should therefore not be used as the sole test for diagnosis. The detection of a rise and/or fall of cardiac biomarkers, with at least one of the values exceeding the 99th percentile of a normal reference population (upper reference limit), in conjunction with symptoms of myocardial ischemia, ST-segment/T-wave changes, wall motion abnormalities on imaging, or presence of coronary thrombus are now required to meet the definition of MI.¹²

MANAGEMENT OF NON-ST-SEGMENT ELEVATION ACUTE CORONARY SYNDROME

Initial Evaluation and Risk Stratification

A 12-lead ECG should be performed and evaluated by a physician within 10 minutes of patient's arrival to the emergency room. If the first tracing proves nondiagnostic in a patient with ongoing symptoms, serial ECGs should be done at 15- to 30-minute intervals for further assessment. Cardiac biomarkers, including cardiac-specific troponins T or I, CPK, and CPK-MB, should be obtained

and repeated to include the time frame of 8 to 12 hours from onset of chest pain. If the initial assessment suggests a diagnosis of ACS, the next step is risk stratification. The TIMI risk score is the most commonly used risk stratification tool, assigning 1 point for each of seven variables (age 65 years or older, three or more risk factors for coronary artery disease [CAD], known coronary stenosis at least 50%, ST-segment deviation at presentation, two or more anginal events in the previous 24 hours, use of aspirin in the previous 7 days, and elevated serum cardiac biomarkers).¹³ Patients with a score of 3 or higher have an exponential increase in short-term ischemic events and benefitted from an early invasive strategy compared with a conservative strategy in the TACTICS-TIMI 18 trial.¹⁴ The GRACE score can also be used to predict hospital and 6-month mortality rates in patients with UA, NSTEMI, and STEMI.¹⁵

Pharmacologic Management

Anti-ischemic Therapy

Table 57-1 shows selected recommendations for anti-ischemic therapy in patients with ACS.¹⁶

Antiplatelet Therapy

Aspirin. Aspirin irreversibly inhibits the COX-1 enzyme in platelets and thus prevents the formation of

thromboxane A₂, one of the mediators of platelet aggregation. Aspirin reduces the incidence of MI in patients with UA compared with placebo,¹⁷ and provides a mortality benefit in patients with STEMI.¹⁸ The minimal effective dose in the Antithrombotic Trialists' Collaboration meta-analysis was 75 mg, which was associated with a 22% reduction in vascular death, MI, and stroke.¹⁹ A dose-dependent increase in bleeding without reduction in thrombotic events was noted with aspirin doses higher than 200 mg.²⁰ Whereas earlier guidelines recommended variable doses of aspirin for maintenance therapy and after percutaneous coronary intervention (PCI), 81 mg per day is now recommended as a reasonable alternative to higher doses (class IIa).²¹

P2Y₁₂ Inhibitors (Clopidogrel, Prasugrel, Ticagrelor). These agents inhibit the binding of ADP to the platelet P2Y₁₂ receptor, thus limiting platelet activation. Adding clopidogrel to aspirin (dual antiplatelet therapy [DAPT]) reduces the incidence of cardiovascular death, MI, stroke, and urgent revascularization in ACS patients treated conservatively or with PCI.²⁰ The incidence of stent thrombosis is also reduced with DAPT compared with aspirin alone. Despite this robust efficacy data, clopidogrel has important shortcomings. It is a prodrug requiring a two-step bioactivation in the liver. The gene encoding the CYP2C19 enzyme responsible for most of this bioactivation demonstrates polymorphism in the general population. Carriers of loss-of-function *2 and *3

TABLE 57-1 Selected Recommendations for Anti-ischemic Therapy

Drug	Class I Recommendation	Class III Recommendation (Contraindicated)
Intravenous nitroglycerin	Administer for 48 hours for persistent ischemia, heart failure, or hypertension.	Systolic BP < 90 mm Hg HR < 50; HR > 100 in the absence of CHF Right ventricular infarction <24 hours of sildenafil <48 hours of tadalafil ANY sign of CHF Low output state
Oral beta blockers	Initiate within 24 hours if no contraindications.	Risk of cardiogenic shock* Advanced conduction disease† Active asthma/reactive airways
IV beta blockers (at any time)	Class IIa recommendation: May administer at any time for HTN if no contraindications.	Systolic BP < 100 mm Hg Do not administer IV ACEIs in the first 24 hours (risk of hypotension).
Oral ACEIs	Administer within 24 hours for pulmonary congestion or LVEF < 40%. ARBs may be given in case of ACEI intolerance (provided no angioedema with ACEI).	Do not administer immediate-release dihydropyridine CCB.
Non-dihydropyridine CCBs	Administer for ongoing/recurrent ischemia when beta blockers are contraindicated.	Do not use because of increased risk of myocardial rupture, CHF, and reinfarction.
NSAIDs		

*Age > 70, sinus tachycardia > 100, systolic BP < 120 mm Hg.

†PR interval > 0.24 sec, second- or third-degree atrioventricular block.

ACEIs, Angiotensin-converting enzyme inhibitors; ARBs, angiotensin receptor blockers; BP, blood pressure; CCBs, calcium channel blockers; CHF, congestive heart failure; HR, heart rate; HTN, hypertension; IV, intravenous; LVEF, left ventricular ejection fraction; NSAIDs, nonsteroidal anti-inflammatory drugs.

From Anderson JL, Adams CD, Antman EM, et al: ACC/AHA 2007 guidelines for the management of patients with unstable angina/non-ST-elevation myocardial infarction: a report of the American College of Cardiology/American Heart Association Task Force on Practice Guidelines (Writing Committee to Revise the 2002 Guidelines for the Management of Patients with Unstable Angina/Non-ST-Elevation Myocardial Infarction) developed in collaboration with the American College of Emergency Physicians, the Society for Cardiovascular Angiography and Interventions, and the Society of Thoracic Surgeons endorsed by the American Association of Cardiovascular and Pulmonary Rehabilitation and the Society for Academic Emergency Medicine. *J Am Coll Cardiol* 50:e1–e157, 2007.

alleles produce a truncated enzyme that results in lack of metabolic activation of clopidogrel and reduced efficacy. These carriers, especially homozygotes, have so-called high on-treatment platelet reactivity (HTPR) and have increased risk of MI and stent thrombosis despite clopidogrel therapy,²² which cannot be overcome by higher doses of clopidogrel.²³ On the other hand, carriers of the *17 allele are “hyper-responders” with an increased risk of bleeding. In addition, clopidogrel also demonstrates variable and overall modest inhibition of platelet aggregation coupled with a slow onset of action.

Newer P2Y₁₂ inhibitors have been developed to overcome these shortcomings. Prasugrel is also a prodrug but requires a one-step bioactivation and does not depend significantly on CYP2C19 for activation. It results in rapid onset of predictable and high-level platelet inhibition. Ticagrelor is a reversible, noncompetitive P2Y₁₂ receptor antagonist, which does not need hepatic activation and results in 85% to 95% platelet inhibition within 2 hours of administration. Both prasugrel and ticagrelor are effective in carriers of reduced-activity CYP2C19 alleles. In the pivotal TRITON-TIMI 38 trial, prasugrel resulted in lower rates of MI and stent thrombosis in patients with moderate- to high-risk ACS, including STEMI, compared with patients treated with clopidogrel.²⁴ Whereas prasugrel was associated with a higher incidence of major bleeding, net benefit still favored prasugrel use, except in three subgroups. Prasugrel had no net benefit in patients older than 75 and/or weighing less than 60 kilograms, and it showed net harm in the subset with prior stroke or transient ischemic attack (TIA). Of note, TRITON-TIMI 38 included only patients whose coronary anatomy had been defined by angiography and who were then selected for PCI. Prasugrel is therefore not currently indicated in conservatively managed patients.

In the PLATO trial, ticagrelor was associated with reduced overall mortality, MI, and stent thrombosis compared with clopidogrel, in patients managed both conservatively and with early PCI.²⁵ Unlike prasugrel, no increase in overall major bleeding was noted compared with clopidogrel. Non-CABG-related major bleeding and fatal intracranial hemorrhage, however, were higher in the ticagrelor cohort. The benefit of ticagrelor was not seen with higher aspirin doses, and concurrent administration of aspirin in doses higher than 100 mg is therefore not recommended.

To minimize bleeding complications, elective coronary bypass surgery (CABG) should be delayed 5 to 7 days after discontinuation of P2Y₁₂ antagonists. In the case of clopidogrel, platelet function testing has also been used to stratify patients to different waiting periods prior to elective CABG. This strategy has resulted in similar postoperative bleeding rates as compared to clopidogrel-naïve patients and reduced waiting periods prior to CABG.²⁶

Class I and III recommendations for oral antiplatelet drugs include the following:

1. An initial dose of 162 to 325 mg aspirin should be chewed (non-enteric-coated, with more rapid absorption) or swallowed (enteric-coated) when the diagnosis of ACS is suspected and should be

continued indefinitely. In the event of aspirin allergy or major gastrointestinal intolerance, an alternative antiplatelet drug should be given.

2. A loading dose, followed by maintenance doses, of either clopidogrel or ticagrelor, is recommended for all patients with medium- to high-risk definite ACS, regardless of initial invasive or conservative management strategy. Prasugrel is an alternative in patients in whom PCI is planned. These drugs should be given as early as possible before PCI or at the time of PCI, and no later than 1 hour after PCI.
3. Clopidogrel or ticagrelor should be given for 12 months in patients managed either conservatively or with PCI, whereas prasugrel should be given, for 12 months, only in post-PCI patients.
4. If the risk of bleeding outweighs expected benefits, P2Y₁₂ inhibitor therapy should be interrupted earlier than 12 months.
5. Prasugrel is contraindicated in patients with prior stroke, TIA, and active bleeding. It can be given to selected patients older than 75 years, provided benefits are expected to outweigh the risks (history of diabetes or prior MI). A lower maintenance dose of 5 mg/day is recommended for patients weighing less than 60 kilograms, although this has not been prospectively studied.

Novel Antiplatelet Agents (Cangrelor, Protease-Activated Receptor-1 Inhibitors). Cangrelor is an intravenous adenosine triphosphate (ATP) analogue that functions as a reversible competitor P2Y₁₂ inhibitor. Onset of action is immediate, and because of a short half-life of 3 to 6 minutes, there is full recovery of platelet function within 60 minutes. Compared to clopidogrel, cangrelor infusion started pre-PCI and continued for at least 2 hours or the duration of PCI, whichever was longer, was associated with lower rates of a composite ischemic endpoint (OR 0.78, 0.66-0.93, $P = 0.005$), without an increase in severe bleeding.²⁷ In this study 43% of patients had ACS. In another study, infusion of cangrelor maintained low levels of platelet reactivity in patients in whom clopidogrel had been interrupted prior to CABG surgery.²⁸ Cangrelor was discontinued 1 to 6 hours prior to CABG surgery and did not result in increased bleeding rates. Cangrelor is not currently commercially available in the United States but may have a future role in patients requiring PCI or awaiting surgery because of reliable absorption and platelet inhibition and its “on-off” effect.

Unfortunately, the incidence of major adverse cardiovascular events and major bleeding remains in the range of 10% to 11%, despite use of newer P2Y₁₂ receptor antagonists. Therefore, novel targets for platelet inhibition are being developed. Thrombin is a potent platelet activator and acts mostly via the protease-activated receptor 1 (PAR-1). PAR-1 inhibitors block thrombin-mediated platelet activation without disrupting thrombin-mediated cleavage of fibrinogen to fibrin. This property allows preservation of physiologic hemostasis. Clinical trials investigating the combination of a PAR-1 antagonist with aspirin and clopidogrel have shown mixed results. The

TRA-PCI study, a phase II trial in patients undergoing elective PCI, did not show an increased risk of bleeding compared with placebo.²⁹ However, the TRACER trial, a phase III study, showed a higher incidence of major bleeding and intracranial hemorrhage when a PAR-1 antagonist was given along with aspirin and a thienopyridine in patients with ACS.³⁰ The role of PAR-1 antagonists in the contemporary management of ACS and PCI is therefore not defined and further studies are required.

Glycoprotein IIb/IIIa Inhibitors

The GP IIb/IIIa receptor is abundant on the platelet surface ($\approx 50,000$ copies per cell) and undergoes a conformational change following platelet activation, allowing it to bind to fibrinogen.³¹ Fibrinogen cross-links multiple activated platelets by this mechanism. These receptors therefore represent the final common pathway of platelet aggregation, regardless of mode of platelet activation. By inhibiting these receptors, GPIs produce rapid and high levels of inhibition of platelet aggregation. Table 57-2 summarizes the three most commonly used GPIs.

Multiple randomized controlled trials have shown that GPIs clearly reduce ischemic complications in ACS patients managed with an invasive strategy, driven primarily by reduction in peri-PCI elevation of CPK.^{32,33} Whereas 48- to 72-hour infusions of tirofiban and eptifibatide reduced the incidence of death and nonfatal MI during the period of medical stabilization before PCI, prolonged administration of abciximab for 48 hours prior to PCI resulted in worse outcomes in the GUSTO IV ACS trial.³⁴⁻³⁶ Abciximab is therefore not indicated for prolonged (>24 hours) administration before PCI or in a planned medical management strategy for patients with ACS.

Although GPIs decrease ischemic events in PCI for ACS, routine use of these agents has waned in recent years for several reasons. Use of GPI incurs an increased risk of major bleeding,³¹ and bleeding after PCI has now been associated with increased 1-year mortality.³⁷ In addition, the pivotal ACUTY trial has now demonstrated that bivalirudin, a direct thrombin inhibitor, administered without GPI at the time of PCI improves the net clinical outcome of bleeding plus ischemic complications compared to heparin plus GPI.³⁸ Current pervasive use of P2Y12 inhibitors in early ACS management

may also dilute the historically observed benefit of up-front platelet inhibition with GPI. In the EARLY-ACS trial of high-risk ACS patients, upstream GPI administered for a median duration of 21 hours in conjunction with DAPT before PCI, was not superior to selective downstream GPI use.³⁹ A 42% increase in major hemorrhage was noted with upstream GPI. In the ACUTY-Timing trial, compared to upstream GPI, deferred selective GPI at the time of PCI lowered major bleeding by 20% with a nonsignificant increase in the endpoint of composite ischemia.⁴⁰ The 2012 update of the 2007 ACS guidelines focuses on rapid loading with potent oral antiplatelet agents rather than routine upstream GPI use. GP IIB/IIIA antagonists are recommended as a possible alternative to P2Y12 inhibitors before PCI in patients managed with an initial invasive strategy, and GPI may be added to oral antiplatelet therapy in patients who develop refractory ischemia while being managed conservatively. Otherwise, selective GPI use is recommended only during PCI.

Selected recommendations for GPI include:

1. At the time of PCI (class I).
2. As an alternative to a P2Y12 inhibitor in patients initially managed conservatively who develop signs and symptoms of ischemia, CHF, or ventricular tachycardia (VT). (Class IIa)
3. The use of upstream GPI may be considered in high-risk patients already receiving aspirin and a P2Y12 receptor inhibitor who are selected for an invasive strategy, such as those with elevated troponin levels, diabetes, or significant ST-segment depression, and who are not otherwise at high risk for bleeding. (Class IIb)
4. Abciximab should not be administered to patients in whom PCI is not planned. (Class III, no benefit)
5. In UA/NSTEMI patients who are at low risk for ischemic events (TIMI risk score ≤ 2) or at high risk of bleeding and who are already receiving aspirin and a P2Y12 receptor inhibitor, upstream GPIs are not recommended. (Class III, no benefit)

Antithrombotic Therapy

Unfractionated Heparin. Unfractionated heparin (UFH) is a naturally occurring glycosaminoglycan, which in its clinically used form consists of a heterogeneous mix

TABLE 57-2 Features of GPIs in Clinical Use

Name	Structure	Half-Life	Reversibility	Data in ACS
Abciximab	Chimeric human-murine monoclonal antibody Irreversible, noncompetitive inhibition of GP IIb/IIIa receptor	Initial: 10 min, second phase: 30 min	Platelet function recovers over 48 hr. BT returns to <12 min within 12-24 hr of discontinuation. Effect can be overcome with platelet infusion.	EPIC ³² GUSTO-ACS ³⁶
Eptifibatide and tirofiban	Synthetic "small molecules"	2-3 hr	Platelet function returns to normal within 4-8 hr of discontinuation. Effect cannot be reversed with platelet transfusion.	PRISM-PLUS ³⁴ PURSUIT ³⁵

BT, Bleeding time; GPIs, glycoprotein inhibitors.

of polysaccharide chains (mean weight 15,000 daltons). Approximately one third of chains contain a unique pentasaccharide sequence, which binds to and causes a conformational change in antithrombin (AT). This accelerates by 1000 fold the interaction of AT with factor Xa and accounts for its anti-Xa activity. To inactivate thrombin (IIa), heparin binds to both AT and IIa to form a ternary complex. Most of the chains in UFH have the more than 18 saccharide units required to form this ternary complex. Consequently, UFH has equal activity against factors IIa and Xa. Heparin is cleared by the reticuloendothelial system and by the kidneys. Its half-life is approximately 1.5 hours, dose dependent and prolonged in renal disease. The first randomized evaluation of heparin in UA compared outcomes in patients who were randomized to placebo, aspirin alone, heparin alone, or aspirin and heparin in combination.¹⁷ UFH alone (5000-U bolus, followed by 1000 U/hr) reduced the incidence of refractory angina, MI, and death compared with placebo. Similar reductions were noted with aspirin alone and the combination of aspirin and heparin. Heparin was noted to be particularly effective in reducing the incidence of MI to 0.8%, compared with 11.9% with placebo.

Low-Molecular-Weight Heparin. LMWH consists of fragments of UFH with a mean molecular weight of 5000 daltons (hence the name *low-molecular-weight heparin*). Less than half of the chains in LMWH have the 18 saccharide units required to form a ternary complex with AT and IIa. Consequently, LMWH has greater anti-Xa activity compared with anti-IIa activity. The anti Xa:IIa activity ratio of enoxaparin is 3.8:1. Its half-life is 2 to 4 hours after intravenous injection and 3 to 6 hours after subcutaneous injection, and anti-Xa activity persists longer than anti-IIa activity. In the SYNERGY trial, high-risk ACS patients were randomized to enoxaparin or UFH.⁴¹ Enoxaparin was associated with a reduced incidence of death and MI compared with UFH in patients who either did not receive pre-randomization anticoagulant therapy or who received the same pre-randomization anticoagulant therapy as that assigned in the study. Changing anticoagulant therapy between UFH and enoxaparin during the course of treatment was associated with increased risk of bleeding and lack of clinical benefit. In a meta-analysis of six trials comparing LMWH to UFH in ACS, the composite endpoint of death and nonfatal MI was significantly lower with LMWH at 30 days (10.1% vs. 11%, OR 0.91 [0.83-0.99]) with a more robust benefit in patients not receiving pre-randomization antithrombotic therapy.⁴² Although enoxaparin can be used safely during PCI, point-of-care anti-Xa level assays are generally not available to monitor the level of anticoagulation. Therefore, most interventionalists prefer a direct thrombin inhibitor or UFH. Vascular sheath removal should be delayed for 4 to 6 hours after an intravenous dose of enoxaparin, and for 6 to 8 hours after a subcutaneous dose.

Fondaparinux. Fondaparinux is a synthetic factor Xa inhibitor that inhibits the multiplier effects of downstream coagulation reactions and reduces the amount of thrombin generated. It is a relatively new addition to the

class I recommended anticoagulants for UA/NSTEMI. The OASIS trial randomized 20,078 patients with UA/NSTEMI to fondaparinux 2.5 mg subcutaneously (SQ) once daily versus enoxaparin 1 mg/kg SQ twice a day.⁴³ Fondaparinux was not inferior to enoxaparin for the primary efficacy outcome of death, MI, or refractory ischemia at 9 days, with a 1.9% absolute reduction in major bleeding compared with enoxaparin. Importantly, a threefold higher incidence of guide catheter thrombus was noted during PCI (performed in 37% of patients) with fondaparinux monotherapy. It is therefore recommended that additional UFH be administered during PCI in patients on fondaparinux.

Bivalirudin. As a direct thrombin inhibitor, bivalirudin directly inhibits (without requiring antithrombin III) both circulating and clot-bound thrombin. Unlike UFH, it does not activate platelets, and it has a short half-life (25 minutes). In the ACUTY trial, bivalirudin reduced major bleeding by almost half, compared with heparin plus GPI in ACS patients undergoing PCI.³⁸ Bivalirudin was also not associated with increased ischemic complications, provided patients were pretreated with clopidogrel prior to PCI. On the other hand, patients with ACS who underwent PCI and without pretreatment with a thienopyridine, tended to have a higher incidence of ischemic events with bivalirudin monotherapy compared with heparin plus GPI. ACUTY excluded ACS patients, who received angiography after 72 hours or were managed conservatively. Therefore, bivalirudin is not approved for use in either of these situations. Major clinical trials of bivalirudin are summarized in Table 57-3.^{38,44,45}

Class I recommendations for antithrombotic therapy include:

1. In patients managed with an early invasive approach, anticoagulant therapy with UFH, LMWH (enoxaparin), bivalirudin, or fondaparinux should be added to antiplatelet therapy as soon as possible.
2. In patients managed with a conservative approach, bivalirudin is not recommended. Fondaparinux, UFH, or LMWH can be used, although fondaparinux is specifically recommended for patients who are at increased risk of bleeding.
3. It is reasonable to proceed with PCI with bivalirudin as sole therapy in patients who were pretreated with at least 300 mg of clopidogrel administered at least 6 hours prior to PCI.
4. Discontinue anticoagulant therapy after PCI for uncomplicated cases.
5. For UA/NSTEMI patients in whom medical therapy is selected as a management strategy and in whom coronary artery disease was found on angiography, continue intravenous UFH for at least 48 hours or until discharge if given before diagnostic angiography, and enoxaparin for duration of hospitalization, up to 8 days, if given before diagnostic angiography.
6. For UA/NSTEMI patients, in whom CABG is selected as a postangiography management strategy, continue UFH. Discontinue enoxaparin 12 to 24 hours before CABG and dose with UFH per institutional practice.

TABLE 57-3 Selected Major Trials of Bivalirudin

Name of Trial	Study Design	Efficacy Outcome	Safety Outcome	Comments
REPLACE-2 ⁴⁴	Urgent or elective PCI: 14% UA N = 6010 1. Bivalirudin + provisional GPI 2. UFH + planned GPI	30-day death/MI/ urgent TVR/ major bleed 9.2% 10% P = 0.32	Major bleeding 2.4% 4.1% P < 0.001	Nonsignificant trend toward lower 1-year mortality with bivalirudin in all patient subgroups with greatest magnitude of benefit among high-risk patients.
ACUITY ³⁸	ACS Mandated angiography ≤ 72 hr N = 13,819 1. UFH/LMWH +/- upstream GPI 2. Bivalirudin +/- upstream GPI 3. Bivalirudin alone	11.7% 11.8% 10.1% P = 0.02 for 3 vs. 1	5.3% 5.7% 3.0% P < 0.001 for 3 vs. 1	In 3304 patients, not pretreated with clopidogrel before angiography or PCI, composite ischemic event rate was 9.1% in the bivalirudin-alone group vs. 7.1% in the heparin plus GPI group (P for interaction = 0.054)
ACUITY-PCI ⁴⁵ 4545	PCI patients in ACUITY N = 7789 1. UFH/LMWH +/- upstream GPI 2. Bivalirudin +/- upstream GPI 3. Bivalirudin alone (provisional GPI 9%)	13% 15% 12% P = 0.057 for 3 vs. 1	7% 8% 4% P < 0.0001 for 3 vs. 1	77% had elevated cTNI or ST deviation. Median time to PCI was 19.6 hours. Similar composite ischemia, but trend for better net clinical outcome with bivalirudin alone. 30-day ischemic endpoint higher with bivalirudin alone in those receiving no pre-/post-PCI clopidogrel.

cTNI, Cardiac troponin I; GPI, glycoprotein inhibitor; LMWH, low-molecular-weight heparin; MI, myocardial infarction; PCI, percutaneous coronary intervention; TVR, target vessel revascularization; UFH, unfractionated heparin.

Oral Anticoagulants. Despite potential benefits, oral anticoagulants are generally not used for ACS treatment because of increased bleeding with warfarin and hepatotoxicity with the factor IIa inhibitor ximelagatran. Rivaroxaban, an oral factor Xa inhibitor, was recently studied as adjunctive treatment for ACS (including STEMI) after initial stabilization with revascularization or medical therapy. Rivaroxaban added to background DAPT with aspirin and clopidogrel for a mean duration of 11 months reduced the composite endpoint of cardiac death, MI, and stroke by 16% and stent thrombosis by 31% compared to placebo.⁴⁶ Patients with prior stroke, TIA, and intracranial hemorrhage were excluded. At a dose of 2.5 mg twice daily, the drug reduced cardiac and all-cause mortality by 32% to 34% compared with placebo but was associated with an increase in non-CABG-related major hemorrhage. Very low-dose oral anticoagulation may therefore be useful in post-ACS patients who are not at high risk of bleeding.

The need for DAPT in patients requiring long-term oral anticoagulation therapy (OAT) is noted frequently in patients with ACS. The combination of DAPT and OAT, known as “triple therapy,” significantly increases risk of overall bleeding compared with DAPT alone (15.5% vs. 3.7%, $P = 0.02$).⁴⁷ In patients who would typically be treated with triple therapy, the WOEST trial demonstrated a marked reduction in bleeding using a combination of clopidogrel and warfarin, compared with the combination of aspirin, clopidogrel, and warfarin (19.5% vs. 44.9%, hazard ratio [HR] 0.36, [0.26-0.50], $P < 0.001$).⁴⁸ All-cause mortality was lower without increased risk of ischemic complications.

Invasive Management

In parallel with institution of anti-ischemic, antiplatelet, and anticoagulant therapies, patients hospitalized with NSTEMI/ACS are triaged to one of two management pathways.

1. Early invasive strategy: patients (a) are taken urgently from the emergency room to the cardiac catheterization laboratory because of ongoing chest pain or hemodynamic instability, despite absence of ST elevation on the ECG, or (b) undergo early but nonurgent coronary angiography within 72 hours of admission.
2. Initial conservative/selective invasive strategy: patients are managed medically, with angiography reserved for those who fail pharmacologic therapy or have a concerning stress test.

Symptoms and signs of ischemia, risk scores (TIMI and GRACE), and patient preferences drive the strategy selection. In high-risk patients, the early invasive pathway generally yields a lower incidence of death/MI and refractory ischemia compared to a conservative strategy. High-risk criteria are outlined in [Table 57-4](#).

Recommendations for an early invasive strategy:

Refractory angina or hemodynamic or electrical instability (without serious comorbidities or contraindications to such procedures)

In initially stabilized patients (without serious comorbidities or contraindications to such procedures) who have an elevated risk for clinical events (see [Table 57-4](#))

TABLE 57-4 Criteria for Selection of Management Strategy

Preferred Strategy	Patient Characteristics
Invasive	High-risk criteria, which include one or more of the following: • Recurrent angina or ischemia at rest/with low-level activity despite intensive medical therapy • Elevated cTNI/cTNT • New ST-segment depression • Signs or symptoms of CHF or new or worsening MR • High-risk noninvasive test findings • Hemodynamic instability • Sustained VT • PCI within 6 months • Prior CABG • High risk score (e.g., TIMI, GRACE) • LVEF < 40%
Conservative	• Low risk score (e.g., TIMI, GRACE) • Patient or physician preference in absence of high-risk features

CABG, Coronary artery bypass grafting; CHF, congestive heart failure; cTNI/cTNT, cardiac troponin I/cardiac troponin T; LVEF, left ventricular ejection fraction; MR, mitral regurgitation; PCI, percutaneous coronary intervention; VT, ventricular tachycardia.

From Anderson JL, Adams CD, Antman EM, et al: ACC/AHA 2007 guidelines for the management of patients with unstable angina/non-ST-elevation myocardial infarction: a report of the American College of Cardiology/American Heart Association Task Force on Practice Guidelines (Writing Committee to Revise the 2002 Guidelines for the Management of Patients with Unstable Angina/Non-ST-Elevation Myocardial Infarction) developed in collaboration with the American College of Emergency Physicians, the Society for Cardiovascular Angiography and Interventions, and the Society of Thoracic Surgeons endorsed by the American Association of Cardiovascular and Pulmonary Rehabilitation and the Society for Academic Emergency Medicine. *J Am Coll Cardiol* 50:e1–e157, 2007.

Recommendations *against* an early invasive strategy:

An early invasive strategy is *not* recommended in patients with extensive comorbidities (e.g., liver or pulmonary failure, cancer), in whom the risks of revascularization and comorbid conditions are likely to outweigh the benefits of revascularization, or in patients who will not consent to revascularization regardless of the findings.

These two approaches have been compared in individual trials and meta-analyses. Whereas individual trials have shown discrepant results, meta-analyses have shown the early invasive approach resulted in reductions in death, MI, angina, and hospitalization among patients with UA.⁴⁹ Practical advantages of an early invasive approach include identification of patients with left main or three-vessel CAD with left ventricular ejection fraction (LVEF) of less than 40%, who will benefit from CABG, and the 10% to 20% of patients who have no significant angiographic CAD.

In addition, early PCI of unstable coronary lesions may prevent ischemic events on medical therapy. This hypothesis was tested in a trial of 410 patients who were randomized to early (median 2.4 hours) versus delayed (median 86 hours) angiography and revascularization.⁵⁰

Despite intensive treatment with antiplatelet and anticoagulant therapy, the delayed group had a higher incidence of death and large MI during the “cooling off” period. A larger trial of 3031 patients with high-risk ACS showed that early (median 14 hours from presentation) angiography and intervention reduced the secondary endpoint of refractory ischemia by 30% compared to a delayed approach (median 50 hours).⁵¹ The largest benefit was noted among patients in the highest tertile of the GRACE risk score (>140). These patients had a 35% reduction in the combined primary endpoint of death, MI, and stroke (number needed to treat 14). Patients with a GRACE score of 140 or lower did not experience a reduction in this primary outcome. The TACTICS-TIMI 18 trial also showed that the benefit of early intervention was confined to higher risk patients (cTNT > 0.01 ng/mL, ST-segment deviation, and TIMI risk score ≥ 3).¹⁴ When an invasive strategy is selected in NSTEMI/ACS, angiography should be performed early, but immediate catheterization does not appear to be necessary. In the ABOARD trial, angiography and PCI at a median of 70 minutes from randomization did not improve outcomes compared with a delay of approximately 24 hours.⁵²

The following general observations can be made from analysis of contemporary trials comparing early versus delayed angiography.

1. Early angiography reduces refractory ischemia, which if left untreated is associated with more than a fourfold risk of MI.
2. Patients at the highest risk, for example, with a GRACE score higher than 140 and TIMI risk score of higher than 3, have the most to gain from an early invasive approach.
3. In high-risk patients, prolonged (>72 hours) “cooling off” with medical therapy is not effective and may be associated with harm, as seen in the ISAR-COOL trial.⁵⁰
4. Therefore, angiography and intervention within 24 hours of presentation represents a reasonable balance between too early and too late.

ST-ELEMENT ELEVATION MYOCARDIAL INFARCTION

Definition

STEMI is universally defined as new ST-segment elevation at the J point in two contiguous leads with the following cutpoints: 1 mm or greater in leads other than V2–V3; in leads V2–V3, ST elevation of 2 mm or greater in men older than 40 years or 1.5 mm or greater in women is required for diagnosis.¹² Other findings indicative of evolving STEMI include a new LBBB in the presence of symptoms of ischemia or horizontal ST depression in leads V1–V3 (transmural posterior injury current).

Risk Assessment

The TIMI risk index, a modification of the TIMI risk score is calculated by the following equation: heart rate × [age/10]²/systolic blood pressure.⁵³ This risk index

Risk Index	Risk Group	Risk of Death		
		24 hr	In-hospital	30 days
≤12.5	1	0.2	0.6	0.8
>12.5-17.5	2	0.4	1.5	1.9
>17.5-22.5	3	1.0	3.1	3.3
>22.5-30	4	2.4	6.5	7.3
>30	5	6.9	15.8	17.4

1) Calculate risk index* 2) Assign risk group 3) Mortality estimate (data from InTIME II)

*Heart rate $\times$ (Age/10)² / Systolic blood pressure. Heart rate in beats per min; systolic blood pressure in mm Hg.

FIGURE 57-3 ■ Correlation between TIMI risk index and short-term mortality in patients with ST-segment elevation myocardial infarction. (From Morrow DA, Antman EM, Giugliano RP, et al: A simple risk index for rapid initial triage of patients with ST-elevation myocardial infarction: an InTIME II substudy. *Lancet* 358:1571–1575, 2001.)

appears to be an independent predictor of 24-hour and 30-day mortality ($P < 0.0001$) with an average 43% relative increase for each 5-point rise in the risk index after adjusting for other major predictors of mortality (Fig. 57-3). The Killip classification has also been used for risk assessment in both STEMI and NSTEMI. The four Killip classes are class I (no evidence of pulmonary congestion or shock), class II (mild pulmonary congestion or S3), class III (pulmonary edema), and class IV (hypotension/shock).⁵⁴

Reperfusion Therapy

Reperfusion therapy consists of fibrinolytic therapy, primary PCI, or some combination of the two, referred to as “facilitated PCI.” Although early reperfusion is critical to management of patients with STEMI, data from the CRUSADE registry suggest that 7% of eligible patients do not receive this therapy.⁵⁵ Very old patients, women, and patients on dialysis are particularly likely to receive delayed reperfusion therapy or none at all.

Fibrinolytic Therapy

Fibrinolytic therapy is most effective if it is administered within the first 1 to 2 hours from symptom onset (the “golden hour”). In this situation, it can be more effective than delayed primary PCI. In fact, prehospital fibrinolysis is associated with a 17% reduction in all-cause mortality compared with hospital-based therapy.⁵⁶ Contemporary fibrinolytic agents include tenecteplase (TNK-tpa), administered as a single weight-based bolus, and reteplase, given as two 10-unit intravenous boluses 30 minutes apart. Both result in establishment of TIMI 2 or 3 flow in approximately 85% of patients.^{57,58} Absolute contraindications include prior intracranial hemorrhage, known cerebral vascular lesion/neoplasm, ischemic stroke within 3 months, intracranial/spinal surgery within 2 months, closed head/facial trauma within 3 months, suspected aortic dissection, severe uncontrolled hypertension (HTN), and active bleeding/diathesis.

The following are recommendations for fibrinolytic therapy, based on the most recent 2013 STEMI guidelines.

1. Onset of symptoms less than 12 hours from presentation with no contraindications to fibrinolysis and delay to primary PCI greater than 120 minutes from first medical contact. (Class I recommendation)
2. Onset of symptoms 12 to 24 hours from presentation, with ongoing ischemia (as evidenced by symptoms or ECG) and either large area of myocardium in jeopardy or hemodynamic instability, without capability for primary PCI. (Class IIa recommendation)
3. Fibrinolytic therapy should NOT be administered in the presence of contraindications or in the presence of ST depression alone (unless a true posterior MI is suspected). (Class III recommendation)

Antiplatelet agents and anticoagulants are administered with fibrinolytics on first medical contact with the intention of improving patency of the coronary artery and preventing reocclusion after successful fibrinolysis. Current recommendations include:

1. Aspirin: 162- to 325-mg loading dose, preferably chewed as a non-enteric-coated formulation. This is followed by 81 to 325 mg indefinitely.
2. Clopidogrel: 300-mg loading dose for patients younger than 75 years and no loading dose for patients older than 75 years. A 75-mg daily maintenance dose is continued for a minimum of 2 weeks and ideally 1 year in the absence of bleeding.
3. UFH: initial bolus of 60 U/kg (maximum 4000 U) and infusion of 12 U/kg/hr (maximum 1000 U/hr), adjusted to keep partial thromboplastin time (PTT) between 1.5 and 2 times control for 48 hours or until revascularization. UFH is most commonly used in the United States. Alternatives include enoxaparin or fondaparinux, both given for a total of 8 days or until revascularization. Enoxaparin dosing is 30 mg IV followed by 1 mg/kg SQ every 12 hours in patients younger than 75 years, or 0.75 mg/kg SQ every 12 hours without an IV bolus in those older than 75 years. Fondaparinux is administered 2.5 mg IV on day 1, followed by 2.5 mg SQ starting on day 2. In the setting of renal impairment, these agents should be avoided or dosing should be reduced.

Rescue Percutaneous Coronary Intervention

Ongoing chest pain and the absence of a reduction in the height of ST elevation by at least 50% in the worst lead by 60 to 90 minutes after fibrinolytic therapy should prompt immediate transfer to a PCI-capable hospital for “rescue” PCI, especially when a large area of myocardium is in jeopardy (such as anterior MI, or extensive inferior MI with right ventricular involvement) and definitely in the presence of hemodynamic or electrical instability (cardiogenic shock, heart failure, ventricular arrhythmias). The REACT trial showed a reduction in reinfarction with rescue PCI compared with conservative management or repeat fibrinolysis.⁵⁹ Rescue PCI has

been given a class IIa recommendation (reasonable to perform).

Routine Percutaneous Coronary Intervention after Successful Fibrinolysis

A strategy of early (<24 hours after fibrinolytic therapy) coronary angiography with or without PCI has been compared with the approach of reserving early PCI for failure of fibrinolytic therapy (rescue PCI) in multiple randomized controlled trials. A meta-analysis of seven randomized trials showed a reduction in the combined endpoint of death and reinfarction at 30 days and 6 to 12 months with early PCI compared to delayed PCI, without an increase in major bleeding.⁶⁰ Therefore, routine coronary angiography and PCI can be performed without increased risk and with potential benefit within 3 to 24 hours of successful fibrinolytic therapy, but should not be performed routinely immediately after fibrinolysis (which is referred to as facilitated PCI, discussed later). This approach has been given a class IIa recommendation (reasonable to perform). High-risk STEMI patients initially treated with fibrinolytic therapy at hospitals without PCI capabilities should be transferred immediately to a PCI-capable hospital for early angiography. In one randomized study, this approach lowered the combined endpoint of death, reinfarction, recurrent ischemia, CHF, and shock, compared to the more conservative approach of delayed angiography or selective transfer for rescue PCI.⁶¹

Delayed Percutaneous Coronary Intervention

In patients who underwent initial successful fibrinolysis or those who never received fibrinolysis, coronary angiography and PCI are strongly recommended (class I recommendation) for patients with any one of the following:

1. Cardiogenic shock or acute severe heart failure that develops after initial presentation
2. Spontaneous or easily provoked myocardial ischemia
3. Intermediate or high-risk findings on predischarge stress testing

Delayed PCI of a totally occluded infarct artery more than 24 hours after onset of STEMI in stable patients is not indicated (class III, no benefit).⁶²

Facilitated Percutaneous Coronary Intervention

This term refers to planned immediate coronary angiography and PCI following administration of a full or half dose of fibrinolytic agent combined with GP. Contemporary trials of this strategy have shown no benefit or net harm.^{63,64} Therefore, this strategy is discouraged in the recent guidelines.

Primary Percutaneous Coronary Intervention

Primary PCI refers to the strategy of catheter-based reperfusion as an initial or primary strategy. Primary PCI

is given a class I recommendation in the following scenarios:

1. In all patients with STEMI presenting within 12 hours of onset of symptoms, as an alternative to fibrinolytic therapy. The goal is a “door-to-balloon” time (time from first medical contact to balloon inflation in the occluded coronary artery) of 90 minutes.
2. In patients with onset of symptoms less than 12 hours from presentation and who have contraindications to fibrinolytic therapy, regardless of the time delay to PCI.
3. Cardiogenic shock or acute severe heart failure irrespective of time delay from the onset of symptoms.

Primary PCI should be restricted to the infarct-related artery, except in the situation of hemodynamic compromise related to ischemia from significant stenosis in the non-infarct-related artery/arteries.

ADDITIONAL CONSIDERATIONS IN ACUTE CORONARY SYNDROME MANAGEMENT

Radial Access for Percutaneous Coronary Intervention

Radial access reduced the composite of death/MI/stroke and non-CABG-related major bleeding by 40% and all-cause mortality by 61% compared with femoral access in patients with STEMI but not in patients with NSTEMI/ACS.⁶⁵ Mortality at 30 days in patients undergoing primary PCI via radial access was only 1.3%, compared with 3.2% with femoral access. There was a 5-minute delay in door-to-balloon time in the radial group. Radial access cut major bleeding and vascular complications by half, in patients with both STEMI and NSTEMI/ACS. Similar findings were noted in the RIFLE-STEMI study, in which radial access resulted in an absolute risk reduction in cardiac mortality by 4% (number needed to treat [NNT] = 25) and bleeding by 4.6% (NNT = 22).⁶⁶ Access site bleeding was 60% lower in the radial group, with no difference in non-access site bleeding.

Implications for Pharmacologic Therapy when Coronary Artery Bypass Grafting Is Required

Clopidogrel and ticagrelor should be discontinued at least 5 days before planned CABG, whereas a longer period of discontinuation of 7 days is recommended for prasugrel. When urgent CABG is required, some studies have shown an increased risk of major bleeding in patients exposed to clopidogrel, whereas others have not.^{67,68} In addition, clopidogrel use before CABG reduced composite ischemia compared with no use before CABG.⁶⁹ In a subgroup analysis of the PLATO trial, rates of major CABG-related bleeding, after stopping clopidogrel or ticagrelor within 1 to 7 days before surgery, were high

but not significantly different from one another.⁷⁰ Prasugrel resulted in greater bleeding post CABG as assessed by chest tube output, compared to clopidogrel but nevertheless was associated with lower mortality.⁷¹ Eptifibatide and tirofiban should be discontinued 2 to 4 hours before urgent CABG and abciximab at least 12 hours before CABG (or reversed with platelet infusion if urgent CABG is needed).

Cardiogenic Shock

Cardiogenic shock is defined as a systolic blood pressure of lower than 90 mm Hg for at least 30 minutes or the need for supportive measures to maintain a systolic blood pressure of 90 mm Hg or higher and end-organ hypoperfusion. Shock occurred in 8.6% of STEMI patients in the large NRM database.⁷² In the pivotal SHOCK trial, mechanical revascularization with either PCI or CABG was associated with improved 6- and 12-month survival compared with fibrinolytic therapy.⁷³ Whereas the SHOCK trial randomized only patients with onset of shock within 36 hours of the MI, the latest guidelines for the management of STEMI recommend emergency revascularization of shock patients with either PCI or CABG, irrespective of the time delay from onset of MI. Fibrinolytic therapy remains a class I recommendation in patients with cardiogenic shock who are unsuitable for PCI or CABG. In addition, whereas the original SHOCK trial demonstrated no benefit of mechanical revascularization in patients older than 75 years, data from the SHOCK registry showed improved survival even in clinically selected older patients.⁷⁴ Therefore, the 2013 guidelines recommend mechanical revascularization in all suitable shock patients without distinction of age.

Postrevascularization Therapy

Cardiac Rehabilitation

A systematic meta-analysis of randomized controlled trials showed a significant reduction in all-cause and cardiac mortality with cardiac rehabilitation.⁷⁵ When only post-MI trials were considered, a 19% reduction in all-cause mortality was noted (OR = 0.81; 95% CI: 0.70–0.93). In this study, benefits were also noted in patients who had undergone surgical or percutaneous revascularization, which supports the value of cardiac rehabilitation even in contemporary patient populations with high rates of mechanical revascularization.

Secondary Prevention

Antiplatelet agents, beta blockers, and statins form the cornerstone of secondary preventive therapy following ACS, whereas angiotensin-converting enzyme inhibitors (ACEIs), angiotensin receptor blockers, and aldosterone receptor antagonists are typically reserved for patients with heart failure, LVEF less than 0.40, or diabetes. Statins should be given to all patients after admission for UA/NSTEMI and STEMI and continued indefinitely in the absence of contraindications. Aggressive LDL reduction with high-dose atorvastatin reduced the composite

endpoint of all-cause death, stroke, MI, UA, and revascularization starting as early as 30 days of therapy, with benefits maintained at 2-year follow-up.⁷⁶ Traditionally the goal low-density lipoprotein (LDL) level has been less than 100 mg/dL, although several trials have shown added benefits of lowering LDL to less than 70 mg/dL.^{76,77}

CONCLUSION

The past few years have seen several important advances in our understanding of the pathophysiology of ACS, platelet biology, pharmacogenomics, and the adverse impact of bleeding, which have resulted in the development of powerful and novel antiplatelet drugs and a focus on reducing bleeding with bivalirudin largely supplanting the use of GPI. This has translated into improved outcomes for patients. The focus in NSTEMI/ACS remains on rapid initiation of anti-ischemic, antiplatelet, and antithrombotic therapy with triage to an early invasive approach for high-risk patients. For STEMI patients, the focus remains on immediate revascularization with concurrent administration of medical therapy.

THE PHARMACOLOGIC MANAGEMENT OF HEART FAILURE

Eric H. Awtry • Wilson S. Colucci

CHAPTER OUTLINE

PATHOPHYSIOLOGY OF HEART FAILURE

Acute Heart Failure
Chronic Heart Failure

PHARMACOLOGIC AGENTS USED IN THE TREATMENT OF HEART FAILURE

Specific Agents
Diuretics
Vasodilators
Neurohormonal Inhibiting Agents
Inotropic Agents
Other Agents
Natriuretic Peptides

APPROACH TO THE MANAGEMENT OF HEART FAILURE

Initial Approach and Clinical Assessment
Pharmacologic Treatment of Chronic Compensated Systolic Heart Failure
Treatment of Decompensated Systolic Heart Failure
Treatment of Diastolic Heart Failure
Flash Pulmonary Edema
Perioperative Heart Failure

Heart failure has become an increasingly important cause of morbidity and mortality in the United States and in other industrialized nations. Despite improvement in heart failure treatment, its prevalence continues to rise, in large part as a result of the aging of the population and the improved survival of heart failure patients. In 2010, the most recent year for which statistics are available, the estimated prevalence of heart failure in the U.S. population over the age of 20 years was 5.7 million. In the same year, heart failure was listed as the primary diagnosis in over 1 million hospital discharges, a number that has remained stable since 2000. The economic impact is staggering, with a yearly cost of caring for these patients estimated at more than \$32 billion, more than half of which is accounted for by direct hospital costs. Despite improvements in therapies, one in five patients will die within 1 year of the initial diagnosis with heart failure, and in the United States alone, heart failure is listed as the principal cause for almost 56,000 deaths annually and as a contributing cause in more than 274,000 deaths.

From a surgical standpoint, heart failure has a significant impact on perioperative morbidity and mortality. Preoperative heart failure is a strong predictor of adverse outcome in patients undergoing noncardiac surgery, and a history of heart failure or depressed left ventricular systolic function is an independent predictor of mortality after coronary artery bypass surgery. A thorough understanding of the pathophysiology and treatment of heart failure is therefore essential for those physicians who manage patients in the perioperative period. Effective

preoperative management of heart failure may prevent perioperative decompensation, and rapid recognition and treatment of postoperative heart failure are essential to prevent progressive pulmonary congestion and organ hypoperfusion. For the well-compensated patient, an understanding of the medical management of chronic heart failure ensures continuation of appropriate therapy both perioperatively and at the time of hospital discharge.

This chapter focuses primarily on the various pharmacologic modalities available for the treatment of heart failure, including their mechanisms of action, benefits as shown in clinical trials, and suggested usefulness in the management of patients with acute and chronic heart failure. The use of many of these pharmacotherapies is based on our current understanding of the pathophysiologic mechanisms underlying heart failure. Therefore, a brief mechanistic overview is provided in an effort to place these therapies in a pathophysiologic context.

PATHOPHYSIOLOGY OF HEART FAILURE

Our understanding of the pathophysiology of heart failure has evolved dramatically during the past 2 decades. The traditional hemodynamic model, although still applicable in the setting of acutely decompensated heart failure, is less relevant in the setting of chronic heart failure, for which the concepts of progressive ventricular remodeling and neurohormonal activation have come to

the forefront. These processes are briefly discussed here as they relate to the pharmacologic treatment of heart failure.

The term *heart failure* does not refer to a single entity; rather, it denotes a syndrome that is characterized by signs or symptoms of intravascular volume overload or manifestations of inadequate tissue perfusion. It is the end result of a variety of cardiac injuries and the ensuing pathologic remodeling that impair the heart's ability to fill with or to eject blood; it may originate from a wide range of disorders of the myocardium, pericardium, endocardium, or intracardiac valves (Table 58-1). Heart failure can be categorized pathophysiologically in several ways.

- *Left-sided heart failure* is characterized by signs and symptoms of pulmonary congestion (dyspnea, orthopnea, pulmonary rales, pleural effusions). *Right-sided heart failure* is characterized by peripheral congestion (elevated jugular venous pressure, peripheral edema, hepatic congestion).
- *Systolic heart failure* refers to that occurring in the setting of left ventricular systolic dysfunction (i.e., reduced ejection fraction). *Diastolic heart failure* refers to that resulting from impaired left ventricular diastolic filling despite normal left ventricular systolic function. These two abnormalities often coexist, although one usually predominates.
- *Acute heart failure* denotes the sudden development of heart failure in the absence of preexisting cardiac dysfunction or the sudden decompensation in a patient with previously stable cardiac disease. This results from an abrupt alteration in cardiac structure or function (e.g., after an acute myocardial infarction or after valvular rupture) and is generally associated with clinical instability. *Chronic heart failure* results from a more indolent process of myocardial dysfunction and may be associated with less clinical severity because of the development of compensatory mechanisms (see later).
- *Low-output heart failure* is that resulting from a reduction in cardiac output (caused by either systolic or diastolic dysfunction) and is usually characterized by venous congestion and increased arterial resistance (i.e., vasoconstriction). *High-output heart failure* occurs in the setting of increased cardiac output (e.g., thyrotoxicosis, anemia, beriberi, Paget disease, arteriovenous fistulas) and is characterized by venous congestion and normal or reduced arterial resistance.
- *Backward heart failure* refers to the hypothesis that the manifestations of heart failure are primarily the result of an accumulation of fluid (and pressure) behind the failing ventricle. *Forward heart failure* proposes that heart failure results from a primary reduction in cardiac output with resultant organ hypoperfusion, sodium and water retention, and subsequent venous congestion. This is not as useful a distinction, because both mechanisms probably operate in most patients with heart failure.

Heart failure may be classified symptomatically on the basis of its clinical severity (Table 58-2). Despite the varied causes and classifications of heart failure, the

TABLE 58-1 Common Causes of Heart Failure

Myocardial

Ischemia or infarction
 Viral myocarditis
 Idiopathic cardiomyopathy
 Hypertrophic cardiomyopathy
 Hypertension
 Toxins (alcohol, cocaine, chemotherapeutic agents)
 Infiltrative diseases (amyloidosis, hemochromatosis)
 Infectious (Lyme disease, Chagas disease)
 Peripartum cardiomyopathy
 Thyroid dysfunction
 Metabolic abnormalities (thiamine or selenium deficiency)

Valvular

Aortic stenosis
 Aortic regurgitation
 Mitral stenosis
 Mitral regurgitation

Arrhythmic

Tachycardia-mediated cardiomyopathy

Pericardial

Constrictive pericarditis

TABLE 58-2 Clinical Classifications of Heart Failure

New York Heart Association Classification

Class I	Symptoms only with greater than usual activity
Class II	Asymptomatic at rest but with symptoms during normal activities
Class III	Asymptomatic at rest but with symptoms during minimal exertion
Class IV	Symptoms at rest

American College of Cardiology/American Heart Association Classification

Stage A	Patients with structurally normal hearts, asymptomatic, but at risk for the development of heart failure resulting from the presence of risk factors (e.g., hypertension, coronary artery disease, diabetes)
Stage B	Patients with structurally abnormal hearts (e.g., left ventricular systolic dysfunction, left ventricular hypertrophy, valvular dysfunction, prior myocardial infarction) but without symptoms of heart failure
Stage C	Patients with structurally abnormal hearts and current or prior symptoms of heart failure
Stage D	Patients with end-stage heart failure symptoms not responsive to standard therapy

manifestations all reflect intravascular volume overload, inadequate tissue perfusion, or their combination. A thorough explanation of all these forms of heart failure is beyond the scope of this chapter. The following discussion, therefore, focuses primarily on left ventricular systolic failure in both the acute and chronic setting.

Acute Heart Failure

The response of the cardiovascular system to the onset of myocardial dysfunction and the pathophysiologic mechanisms underlying the subsequent progression to

heart failure depends in large part on the acuity of the dysfunction. An acute cardiac insult results in a series of hemodynamic alterations that account for the clinical manifestations of left ventricular failure. This occurs irrespective of whether the initial insult depresses myocardial contractility (systolic dysfunction) or impairs ventricular filling (diastolic dysfunction). The cascade begins with a rise in left ventricular end-diastolic pressure. This elevated pressure is transmitted to the left atrium and subsequently to the pulmonary venous and capillary system. The increased intravascular pressure results in transudation of fluid into the pulmonary interstitium where it interferes with gas exchange, resulting in hypoxemia and dyspnea. In addition, there is often an associated reduction in cardiac output resulting in inadequate delivery of blood to the arterial system with resultant organ hypoperfusion.

The heart's response to these hemodynamic alterations is the activation of several compensatory mechanisms (Table 58-3). A rapid, generalized activation of the adrenergic system occurs and is associated with a withdrawal of parasympathetic tone. Direct sympathetic stimulation of the heart and β -adrenergically induced release of epinephrine and norepinephrine from the adrenal glands result in tachycardia and an increase in myocardial contractility, both of which serve to augment cardiac output. Catecholamine-induced peripheral arterial vasoconstriction redirects the available cardiac output away from relatively nonessential organs (i.e., skin, skeletal muscle, gut, kidney) and helps maintain sufficient blood pressure to ensure adequate perfusion of more vital organs (i.e., heart and brain). Furthermore, β -adrenergic stimulation of the juxtaglomerular apparatus in the

kidneys results in the release of renin and activation of the renin-angiotensin system. The angiotensin II thus produced is a potent vasoconstrictor and acts in concert with the direct α -adrenergic stimulation of the vasculature to maintain blood pressure. The reduced renal blood flow from depressed cardiac output and redistribution of blood volume results in activation of renal baroreceptors. This further stimulates renin release and augments sympathetic activation, thereby contributing to vasoconstriction.

In addition to producing these hemodynamic alterations, acute heart failure is characterized by marked sodium and water retention. This occurs through a variety of mechanisms. Angiotensin II directly promotes the reabsorption of sodium in the proximal nephron and indirectly promotes the reabsorption of sodium from the distal nephron, this latter effect being mediated through angiotensin II-induced release of aldosterone from the adrenal cortex. Furthermore, angiotensin II and norepinephrine stimulate hypothalamic release of arginine vasopressin, resulting in further vasoconstriction and free water reabsorption. These changes produce an expansion of intravascular volume and augmentation of venous return, thereby increasing ventricular end-diastolic volume (*preload*). The increased preload results in an increase in stroke volume by the Frank-Starling mechanism (Fig. 58-1) and thereby helps support the cardiac output.

Chronic Heart Failure

In combination, the aforementioned mechanisms serve a compensatory role in acute heart failure, helping to

TABLE 58-3 Compensatory Mechanisms in Heart Failure

Compensatory Response	Stimuli	Beneficial Effects	Adverse Effects	Potential Pharmacologic Interventions
Renin-angiotensin system activation	↓CO/BP ↓Renal blood flow ↑ β -Adrenergic activity	Maintain vital organ perfusion through vasoconstriction and sodium retention	↑Afterload → worsened LV function Adverse LV remodeling (apoptosis, myocyte hypertrophy)	ACE inhibitors ARBs
Adrenergic activation	↓CO/BP	↑CO through ↑ in heart rate and contractility ↑BP	↑Ischemia ↑Afterload → worsened LV function ↑LVEDP → pulmonary congestion Adverse LV remodeling (apoptosis, myocyte hypertrophy)	β -Adrenergic blocking agents
Renal salt and water retention	↑Antidiuretic hormone ↑Norepinephrine ↑Angiotensin II ↑Aldosterone ↓Renal blood flow	↑Preload → ↑stroke volume and CO	Pulmonary and systemic congestion Adverse LV remodeling	Diuretics Aldosterone inhibitors ACE inhibitors, ARBs β -Adrenergic blocking agents
↑Natriuretic peptide secretion	Volume expansion (atrial stretch)	Diuresis Natriuresis Partial inhibition of renin-angiotensin system and norepinephrine	None known	Natriuretic peptides

ACE, Angiotensin-converting enzyme; ARB, angiotensin receptor blocker; BP, blood pressure; CO, cardiac output; LV, left ventricular; LVEDP, left ventricular end-diastolic pressure.

FIGURE 58-1 ■ Frank-Starling curve with normal systolic function and with heart failure and the hemodynamic effect of pharmacologic therapy. In the normal setting, an increase in preload results in an increase in stroke volume. In heart failure, this relationship is blunted, and at any given stroke volume, the preload must be higher (*horizontal dotted line*). Similarly, for any given preload, the stroke volume is lower (*vertical dotted line*). Diuretic therapy (D) reduces preload without a significant effect on stroke volume, whereas inotropic therapy (I) augments stroke volume without an appreciable effect on preload. Vasodilator therapy (V) has moderate beneficial effects on both preload and stroke volume; however, the greatest effects are seen with combination therapy (I + V, I + V + D).

maintain cardiac output and blood pressure to allow adequate perfusion of vital organs. These compensatory mechanisms may initially be adequate to allow clinical stability, and the patient may subsequently go through a stage of asymptomatic ventricular dysfunction, maintained in part by chronic stimulation of the adrenergic and renin-angiotensin systems. As heart failure progresses, the hemodynamic overload induces changes in the shape and size of the ventricle, a process known as *ventricular remodeling*. The specific changes that occur depend in part on the hemodynamic stressors facing the ventricle. In predominantly pressure-overloaded conditions (e.g., hypertension, aortic stenosis), there is a rise in systolic wall stress that results in left ventricular hypertrophy. If this hypertrophy is insufficient to normalize the wall stress, dilation occurs. Under conditions of volume overload (e.g., aortic or mitral insufficiency), there is a rise in diastolic wall stress that induces ventricular dilation. This dilation in turn results in increased systolic wall stress (by the Laplace relationship) and subsequent hypertrophy. These hypertrophic changes help maintain systolic wall stress within a normal range and help preserve ventricular contractile function. However, with continued hemodynamic overload, there is progressive ventricular dilation, eventuating in the development of a dilated, spherical heart. This altered ventricular morphology produces less efficient ventricular contraction, may induce mitral regurgitation caused by annular dilation and malcoaptation of the valve leaflets, and is associated with an adverse prognosis.

The stimuli that induce ventricular remodeling are varied and the mechanisms underlying the remodeling process are complex (Table 58-4). It appears that increased

TABLE 58-4 Factors Involved in Ventricular Remodeling

Stimulants of Ventricular Remodeling	Molecular and Cellular Events That Mediate Ventricular Remodeling
Altered hemodynamic load (increased preload, afterload, wall stress)	Myocyte hypertrophy Myocyte loss (necrosis and apoptosis)
β -Adrenergic stimulation	Myocyte "slippage"
Activation of the renin-angiotensin system	Transition to fetal myocyte phenotype
Inflammatory cytokines (e.g., tumor necrosis factor α , interleukins 1 and 6)	Neurohormonal activation Fibroblast proliferation
Vasoactive peptides (e.g., endothelin)	Alterations in the interstitial matrix
Oxidative stress	Alterations in excitation-contraction coupling

wall stress (resulting from ventricular dilation and increased afterload) and neurohormones (i.e., β -adrenergic and renin-angiotensin systems), vasoactive peptides (e.g., endothelin), and cytokines (e.g., tumor necrosis factor α) mediate remodeling. These factors may have direct effects on the cardiac myocytes or may act indirectly through stimulation of second-messenger systems and thereby induce a variety of changes in myocyte structure and function. On a cellular level, myocyte hypertrophy results from the replication of sarcomeres either in parallel (producing ventricular hypertrophy) or in series (producing ventricular dilation). Alterations in the expression of various contractile proteins occur with reexpression of fetal genes and reduced expression of adult contractile genes, resulting in abnormalities of calcium handling and excitation-contraction coupling. Chronic stimulation of the sympathetic system is accompanied by a reduction in the density of β -adrenergic receptors in the myocardium and an uncoupling of the receptors from their intracellular mediators. This results in a blunted response of the failing myocardium to either endogenous (e.g., exercise) or exogenous (e.g., dopamine or dobutamine) adrenergic stimulation.

In addition to these alterations of the contractile apparatus within the myocytes, there is a progressive reduction in the number of myocytes, in part the result of apoptosis induced by the various stimuli of remodeling. Furthermore, changes occur in the extracellular matrix related to fibroblast proliferation, interstitial fibrosis, and increased expression of degradative enzymes such as matrix metalloproteinases. The last factor results in the loss of mechanical coupling of myocytes and may contribute to the remodeling process by facilitating "myocyte slippage" and, thereby, ventricular dilation.

As the remodeling process develops, the neurohormonal effects of the β -adrenergic and renin-angiotensin systems on the peripheral vasculature and renal salt and water handling continue. The intense vasoconstriction, while maintaining flow to vital organs, contributes to hypoperfusion of the kidneys and progressive renal dysfunction. The augmented preload and cardiac output

resulting from sodium and water retention help maintain circulating blood volume and tissue perfusion. However, the associated increase in end-diastolic pressure and increased ventricular wall stress contribute to progressive ventricular remodeling and result in pulmonary and systemic venous hypertension and precipitation of congestive symptoms. Thus, these initially compensatory changes become deleterious in the chronic setting. The inhibition of these processes offers not only a mechanism for the treatment of heart failure but also the potential to reverse the adverse remodeling seen in the chronic state (see [Table 58-3](#)).

PHARMACOLOGIC AGENTS USED IN THE TREATMENT OF HEART FAILURE

Most pharmacologic agents used for the treatment of heart failure effect benefit either by interfering with the hemodynamic alterations described earlier or through inhibition of the neurohormonal activation underlying these alterations (see [Fig. 58-1](#)). These medications fall into several categories: diuretics, vasodilators, inotropic agents, and neurohormonal inhibitors. Diuretics act to reduce preload (leftward shift on the Frank-Starling curve), resulting in decreased filling pressures and improved congestive symptoms. Although this fall in preload may be associated with a reduction in stroke volume, this effect is minimal in patients with elevated filling pressures. Pure venodilators similarly reduce filling pressures and congestive symptoms and have minimal effect on stroke volume. Arterial vasodilators and inotropic agents predominantly augment cardiac output and thereby improve organ perfusion; arterial vasodilators act indirectly through a reduction in vascular resistance,

whereas inotropic agents directly increase contractility and stroke volume. Although the increased cardiac output seen with these agents may result in a fall in filling pressures, the effect may be relatively modest. As a result of the differential effects of these agents, many patients with heart failure attain the greatest benefit from combination therapy. Neurohormonal inhibitors may have mixed hemodynamic effects. The blockade of adrenergic tone (beta blockers) and inhibition of the renin-angiotensin system (angiotensin-converting enzyme [ACE] inhibitors, angiotensin receptor blockers [ARBs]) results in vasodilation and augmented cardiac output. These agents may also decrease preload and reduce filling pressures through a reduction in neurohormonally mediated renal sodium and water retention.

Specific Agents

Diuretics

Diuretics have long played an important role in the symptomatic treatment of heart failure ([Table 58-5](#)). The induced diuresis and natriuresis reduce extracellular volume and ventricular filling pressures, thereby ameliorating congestive symptoms. This effect occurs without a significant decrease in cardiac output or systemic blood pressure unless excessive diuresis and intravascular volume depletion occur. Whereas diuretics are beneficial in controlling symptoms and improving exercise capacity in patients with heart failure, with the exception of aldosterone inhibitors (spironolactone and eplerenone) diuretic use has not resulted in a decrease in mortality.

Loop diuretics act in the thick ascending limb of the loop of Henle, where they inhibit the $\text{Na}^+\text{-K}^+\text{-2Cl}^-$ transporter, resulting in increased delivery of sodium and

TABLE 58-5 Diuretics Commonly Used in the Treatment of Heart Failure

Class and Examples	Daily Dose Range	Duration of Action	Adverse Effects (by Class)
Loop Diuretics			
Furosemide (Lasix)	20-480 mg PO 20-300 mg IV	4-6 hours	Hypokalemia, hyperuricemia, metabolic alkalosis, ototoxicity at high doses
Torsemide (Demadex)	5-200 mg PO	12 hours	
Bumetanide (Bumex)	0.5-5 mg PO	4-6 hours	
Ethacrynic acid (Edecrin)	25-100 mg PO	12 hours	
Thiazide Diuretics			
Chlorothiazide (Diuril)	125-500 mg PO	6-12 hours	Hypokalemia, hyponatremia, hyperuricemia, hyperglycemia, hyperlipidemia
Hydrochlorothiazide (HydroDIURIL)	12.5-50 mg PO	12-18 hours	
Chlorthalidone (Hygroton)	25-100 mg PO	24 hours	
Thiazide-like Diuretics			
Metolazone (Zaroxolyn)	0.5-10 mg PO	24 hours	Hypokalemia, hypomagnesemia
Aldosterone Inhibitors			
Spironolactone (Aldactone)	25 mg PO	8-12 hours	Hyperkalemia, nausea, gynecomastia (spironolactone)
Eplerenone (Inspra)	25-50 mg PO	4-6 hours	
Potassium-Sparing Diuretics			
Amiloride (Midamor)	5-10 mg PO	24 hours	Hyperkalemia when combined with angiotensin-converting enzyme inhibitor or angiotensin receptor blocker
Triamterene (Dyrenium)	50-100 mg PO	12 hours	

water to the distal nephron. They also decrease the tonicity of the medullary interstitium and thereby limit the osmotic reabsorption of free water from the collecting tubules. Currently available loop diuretics include furosemide, bumetanide, torsemide, and ethacrynic acid. Ethacrynic acid carries an increased risk of ototoxicity; therefore, this agent should be reserved for patients who are allergic to or intolerant of other agents.

Furosemide is the loop diuretic most commonly used for the treatment of heart failure. For patients with mild to moderate congestive symptoms, it can be given orally at initial doses of 20 to 40 mg daily. Its bioavailability ranges from 40% to 70%, and gradual dose titration is frequently required. Furosemide has a relatively short half-life. Once renal tubular levels of the drug decline, avid sodium reabsorption occurs throughout the nephron, potentially limiting or preventing effective natriuresis. A twice-daily dosing regimen may therefore be required to produce adequate salt and water loss. In patients with more severe volume retention or decompensated heart failure, intravenous administration of furosemide (20 to 100 mg) may produce a more rapid and effective diuresis. The maximum intravenous dose is 300 mg; however, the risk of ototoxicity increases at such high doses. For patients who require frequent high doses of intravenous furosemide, a continuous infusion may be used and may be associated with less hypotension; however, it does not appear to be any more effective at reducing symptoms or stimulating diuresis than are intermittent intravenous boluses. The infusion is usually started at 5 to 10 mg/hr and titrated as needed to obtain the desired effect. Bumetanide and torsemide have greater bioavailability than does furosemide ($\approx 80\%$) but have not demonstrated better efficacy and are significantly more expensive.

Thiazide diuretics act in the distal convoluted tubule, where they inhibit the $\text{Na}^+\text{-Cl}^-$ cotransporter. Their efficacy is dependent on the delivery of sodium to the distal nephron; therefore, their diuretic effect is limited by sodium reabsorption from more proximal regions, as occurs during intravascular volume depletion or in low-flow states. In addition, they are ineffective when glomerular filtration rates fall below 30 mL/min. Thiazides may be useful as the sole diuretic in treatment of mild congestive symptoms; however, their predominant role in the management of more advanced heart failure is as an adjunct to other diuretic therapy in patients who exhibit diuretic resistance. Although several thiazides are available, the most frequently used are hydrochlorothiazide (12.5 to 50 mg daily) and metolazone (2.5 to 10 mg daily). These agents exhibit synergism with loop diuretics and should be given approximately 30 minutes before administration of furosemide, bumetanide, or torsemide.

Spironolactone is a competitive inhibitor of aldosterone in the distal convoluted tubule, whereas eplerenone is a selective aldosterone blocker. These agents stimulate a mild natriuresis and potassium reabsorption and may be most effective in patients with advanced heart failure, in whom marked activation of the renin-angiotensin-aldosterone system results in aldosterone levels as high as 20 times normal. In the Randomized Aldactone Evaluation Study (RALES), patients with moderate to severe congestive heart failure (NYHA class III-IV) were treated

with spironolactone (25 to 50 mg daily) and had improved symptoms, reduced rates of hospitalization for heart failure, and 30% reduction in mortality. In the Eplerenone Post-Acute Myocardial Infarction Heart Failure Efficacy and Survival Study (EPHESUS), patients with acute myocardial infarction, left ventricular ejection fraction of 40% or less, and evidence of heart failure were treated with eplerenone (25 to 50 mg daily) and had a 15% reduction in mortality and significantly fewer episodes of heart failure. The mechanism of benefit of these agents is unlikely to be related to a diuretic effect because they are relatively weak diuretics. Rather, it probably reflects inhibition of aldosterone-induced myocardial fibrosis and ventricular remodeling. The major side effect of spironolactone is gynecomastia, which is not seen with eplerenone because of its selective mineralocorticoid blockade. The dose of these agents should not exceed 50 mg daily because of the risk of hyperkalemia, especially in patients with a serum creatinine concentration of 2.5 mg/dL or higher or when they are used in conjunction with an ACE inhibitor or ARB for the treatment of heart failure.

Amiloride and triamterene inhibit the reabsorption of sodium in the distal convoluted tubule and proximal collecting duct, resulting in a mild natriuresis and reduction of the ionic gradient required for potassium secretion into the urine. These agents produce a mild diuresis without the potassium wasting seen with loop diuretics and thiazides and may be effective for the control of mild congestive symptoms. However, when they are given alone, they are not effective in maintaining a negative fluid balance in patients with advanced heart failure. In such patients, these agents may provide benefit as part of a combination diuretic regimen, especially given their potassium-sparing properties.

Patients treated with diuretics require close monitoring of their renal function and serum electrolytes. Loop diuretics and thiazides can lead to profound hypokalemia and hypomagnesemia, especially when they are used in combination; spironolactone may result in hyperkalemia. In contrast to loop diuretics, thiazides do not alter the tonicity of the renal medullary interstitium and may produce significant hyponatremia as a result of the reabsorption of free water from the distal convoluted tubule in the face of a preserved interstitial gradient. In addition to these metabolic effects, thiazides may adversely affect serum lipid levels, and spironolactone may induce gynecomastia.

Vasodilators

Nitrovasodilators. Nitric oxide is formed by normal endothelial and smooth muscle cells throughout the vasculature and functions in both a paracrine and an autocrine fashion. Its primary mechanism of action involves an induced increase in intracellular cyclic guanosine monophosphate, which results in vascular smooth muscle relaxation. Nitrovasodilators such as sodium nitroprusside and organic nitrates (i.e., nitroglycerin) are metabolized to nitric oxide within the vasculature. They are potent vasodilators and, as such, are useful in the management of heart failure.

Nitroprusside is the sodium salt of nitric oxide and ferricyanide. It is a balanced vasodilator and produces both vasodilation and venodilation in both systemic and pulmonary systems. These effects result in favorable hemodynamic changes, including a decrease in right atrial and pulmonary capillary wedge pressures (i.e., decreased preload), a reduction in pulmonary and systemic vascular resistance (i.e., decreased afterload), and an increase in stroke volume and cardiac output/index (Fig. 58-2). In contrast to other arterial vasodilators, nitroprusside does not cause a significant increase in heart rate, and its use is usually associated with a decrease in myocardial oxygen demand. Nitroprusside is useful for the management of heart failure associated with elevated filling pressures, low cardiac output, and high vascular resistance, as occurs in patients with decompensated systolic failure. It is also ideally suited for the management of heart failure associated with profound hypertension, acute mitral regurgitation, acute aortic insufficiency, or acute ventricular septal defect.

Nitroprusside is administered as a continuous infusion. Its onset of action is rapid (within 30 seconds), and it reaches peak effect within 2 minutes. Similarly, its effects completely resolve within 3 minutes of discontinuation of its infusion. Because of these rapid changes in hemodynamics, it is best administered under the guidance of pulmonary (i.e., Swan-Ganz catheter) and systemic arterial monitoring. The usual starting dose is 0.1 to 0.25 $\mu\text{g}/\text{kg}/\text{min}$. The dose may be titrated up by 0.25 $\mu\text{g}/\text{kg}/\text{min}$ every 5 to 10 minutes until the desired effect is achieved or the maximum dose is reached (10 $\mu\text{g}/\text{kg}/\text{min}$). The use of nitroprusside may be limited by the development of hypotension, especially in patients with normal left ventricular systolic function or low filling pressures. Rapid cessation of nitroprusside may result in

rebound hypertension, probably reflecting neurohormonal activation. Nitroprusside is metabolized in the vasculature to nitric oxide and cyanide; cyanide is further metabolized in the liver to thiocyanate, which is excreted by the kidneys. Accumulation of these toxic metabolites is more likely to occur when nitroprusside is infused at higher doses or for prolonged periods, especially in the setting of hepatic and renal dysfunction. Cyanide toxicity may be manifested as abdominal pain, confusion, or seizure and is usually preceded by lactic acidosis. Thiocyanate toxicity usually manifests as nausea, confusion, fatigue, psychosis, and, in rare cases, coma. If toxicity is suspected, the infusion should be discontinued and serum levels of the metabolites should be measured. Cyanide toxicity can be treated with sodium nitrite (300 mg) or sodium thiosulfate (12.5 g), but thiocyanate toxicity may require hemodialysis.

Nitroglycerin, like nitroprusside, is a potent vasodilator; however, it has dose-dependent effects in the arterial and venous systems. At low doses, it is a relatively selective venodilator, resulting in increased venous capacitance and decreased left and right ventricular filling pressures. At higher doses, it is also an arterial dilator and results in a fall in pulmonary and systemic vascular resistance, although less predictably and to a lesser extent than nitroprusside. Intravenous nitroglycerin is an effective agent in the management of acute decompensated heart failure characterized by increased filling pressures and elevated vascular resistance. In addition, nitroglycerin has a significant vasodilative effect on epicardial coronary arteries and may indirectly improve left ventricular function by improving blood flow to ischemic myocardium. It is thus an agent of choice in managing heart failure associated with acute myocardial ischemia or infarction.

Intravenous nitroglycerin is usually initiated at 20 $\mu\text{g}/\text{min}$ and titrated up by 10 to 20 $\mu\text{g}/\text{min}$ every 5 to 10 minutes until the desired hemodynamic effect is achieved or the maximum dose is reached (400 $\mu\text{g}/\text{min}$). Its effects are immediate and resolve rapidly after discontinuation of the infusion. Nitroglycerin may result in hypotension, especially at high doses and in patients with low filling pressures. Its use is commonly associated with a headache, occasionally requiring down-titration or discontinuance of the infusion. Nitrate tolerance frequently develops but can usually be overcome by increasing the infusion rate.

Hydralazine. Hydralazine is a direct vasodilator that causes relaxation of arteriolar smooth muscle by an unknown mechanism. It does not cause venodilation or dilation of epicardial coronary arteries; thus, its hemodynamic effects are primarily limited to a reduction in vascular resistance. Hydralazine is an effective antihypertensive agent, especially when it is used in combination with other agents. When it is administered to patients with congestive heart failure, it is most effective in combination with venodilating agents (e.g., organic nitrates). The combination of hydralazine and oral nitrates, when it is added to a regimen of digoxin and diuretics, has been shown in randomized trials to reduce mortality, to improve left ventricular systolic function, and to reduce symptoms in patients with heart failure. However, the

FIGURE 58-2 ■ Comparative hemodynamic effects of maximally tolerated doses of nitroprusside, dobutamine, and milrinone in patients with severe heart failure. CI, Cardiac index; dP/dt, change in pressure per change in time; HR, heart rate; LVEDP, left ventricular end-diastolic pressure; MAP, mean arterial pressure; RAP, right atrial pressure; SVR, systemic vascular resistance. (Modified from Colucci WS, Wright RF, Jaski BE, et al: Milrinone and dobutamine in severe heart failure: differing hemodynamic effects and individual patient responsiveness. *Circulation* 73:11175-183, 1986.)

benefit of this regimen on mortality and left ventricular function is less than that of ACE inhibitors. In general, hydralazine is not a first-line agent for the treatment of heart failure. Nonetheless, it should be considered in patients who are intolerant of ACE inhibitors because of allergy or renal insufficiency, and it is the agent of choice for afterload reduction in pregnant patients. In addition, it may offer further relief in patients with heart failure who remain symptomatic despite treatment with ACE inhibitors.

Hydralazine therapy is initiated at a dose of 10 mg four times daily and titrated upward as blood pressure tolerates to a maximum dose of 100 mg four times daily. Organic nitrates are given concurrently (i.e., isosorbide dinitrate, 30 to 120 mg daily). Hydralazine-induced vasodilation is associated with a baroreceptor-mediated increase in sympathetic activity, resulting in a reflex tachycardia, increased ventricular contractility, increased renin activity, and fluid retention. In patients with underlying coronary artery disease, the arteriolar dilation may result in a coronary steal phenomenon and, combined with the tachycardia, may precipitate myocardial ischemia. Coadministration with β -adrenergic blocking agents may prevent this complication; nonetheless, hydralazine should be used with caution in patients with an ischemia cardiomyopathy. Other side effects occur more frequently and include headaches, flushing, palpitations, nausea, and dizziness. A lupus-like syndrome occurs in 5% to 10% of patients and may require discontinuation of the drug.

Calcium Channel Blocking Agents. In general, the use of calcium channel blocking agents for the treatment of heart failure has been disappointing, despite the fact that they are relatively potent vasodilators. Verapamil and diltiazem have negative inotropic effects and may worsen symptoms in patients with systolic heart failure. However, these agents may improve diastolic function because of their rate-slowing effects and induced alterations in calcium homeostasis and thus may be beneficial in the treatment of diastolic heart failure. The first-generation dihydropyridine nifedipine has been associated with an increase in adverse effects, including a trend toward increased mortality in patients with systolic heart failure. This may relate to neurohormonal activation resulting from fluctuations in its hemodynamic effects, especially with short-acting formulations. Newer second-generation dihydropyridines, such as amlodipine and felodipine, appear to be safe in patients with heart failure but have not demonstrated significant benefit with regard to morbidity or mortality. Therefore, although these agents could be considered for the treatment of hypertension or angina in patients with left ventricular systolic dysfunction, calcium channel blocking agents in general should not be used for primary treatment of heart failure.

Neurohormonal Inhibiting Agents

Angiotensin-Converting Enzyme Inhibitors. ACE inhibitors have a variety of beneficial effects on the pathophysiologic mechanism of heart failure. Hemodynamically, ACE inhibitors are potent vasodilators and

reduce both preload and afterload. The subsequent fall in intracardiac pressures and reduction in wall stress result in a decrease in myocardial oxygen demand, potentially reducing ischemia, and a decrease in the activity of the sympathetic nervous system, thereby reducing electrical instability. In addition, the ACE inhibitor-induced reduction in angiotensin as well as the subsequent reduction in adrenal aldosterone release may have direct effects on the extent of fibrosis and collagen deposition that characterize myocardial remodeling in heart failure. The effects of ACE inhibitors are primarily mediated by inhibition of the enzyme responsible for the conversion of angiotensin I to angiotensin II, thereby decreasing production of angiotensin II. However, some of the benefit of ACE inhibitors may result from their effects on the kinin system; ACE inhibitors decrease the degradation of kinins (e.g., bradykinin) and thereby enhance their vasodilative effects and potentiate kinin-mediated synthesis of vasodilative prostaglandins.

ACE inhibitors have been extensively studied in a wide variety of patients with heart failure and have almost universally demonstrated benefit in hemodynamics, symptoms, exercise capacity, hospitalization, and mortality. In the Cooperative North Scandinavian Enalapril Survival Study (CONSENSUS), patients with severe (NYHA class IV) systolic heart failure who were already treated with digoxin and diuretics had a 40% reduction in mortality at 6 months when treated with enalapril. Patients with less-severe heart failure (NYHA class II-III and an ejection fraction $\leq 35\%$) were studied in the treatment arm of the SOLVD (Studies Of Left Ventricular Dysfunction) trial. In this trial, patients who were treated with enalapril had a 16% reduction in mortality and a 26% reduction in the risk of death or hospitalization for worsening heart failure. In the Acute Infarction Ramipril Efficacy study, patients with symptomatic heart failure, a recent myocardial infarction, and ejection fractions below 40% demonstrated a 27% decrease in mortality after 30 days of treatment with ramipril. Furthermore, several studies have demonstrated that asymptomatic patients with depressed ejection fractions ($<35\%$ to 40%) have reduced morbidity and mortality when treated with ACE inhibitors, although the magnitude of this benefit is less than that seen in patients with overt heart failure. Thus, the results of clinical trials with ACE inhibitors reveal a consistent benefit in patients with symptomatic heart failure or asymptomatic left ventricular dysfunction (Fig. 58-3).

The various ACE inhibitors that are currently available (Table 58-6) differ in plasma half-life, dosing regimen, and ability to inhibit ACE at the tissue level. However, available data suggest that the beneficial effects of these agents are a class effect and not dependent on individual pharmacologic characteristics. Nonetheless, in selecting an ACE inhibitor for the treatment of heart failure, preference should be given to those agents that have demonstrated efficacy in large-scale trials (enalapril, captopril, lisinopril, and ramipril). ACE inhibitors should be initiated at low doses, especially in patients with hypotension before treatment. If initial doses are tolerated hemodynamically, the dose should be gradually titrated upward over several days to several weeks. In general,

FIGURE 58-3 ■ The effect of angiotensin-converting enzyme (ACE) inhibitors on the total mortality (**A**) and total mortality plus readmission for heart failure (**B**) in patients with heart failure or left ventricular systolic dysfunction. OR, Odds ratio. (Modified from Flather MD, Yusuf S, Kober L, et al: Long-term ACE-inhibitor therapy in patients with heart failure or left ventricular dysfunction: a systematic overview of data from individual patients. *Lancet* 355:1575–1581, 2000.)

these agents should be titrated upward to goal doses as determined by clinical trials or to the highest dose that can be tolerated. Although lower doses may offer mortality benefit similar to that of higher doses, higher doses are associated with augmented symptom control. In patients with decompensated heart failure who cannot receive oral agents, intravenous enalaprilat can be used. Enalaprilat is the active form of the oral ACE inhibitor enalapril. When it is given intravenously, it is a balanced vasodilator resulting in a reduction in left and right ventricular filling pressures and vascular resistance.

Use of ACE inhibitors may be limited by the development of side effects. Hypotension is the most common adverse effect, occurs most frequently during the initiation of therapy, and is more common in patients who are volume depleted. It can usually be managed by reducing diuretic dosing and titrating the ACE inhibitor slowly. Moderate hypotension (systolic blood pressure >85 mm Hg) can frequently be tolerated as long as organ hypoperfusion is not present. ACE inhibitors produce vasodilation of renal efferent arterioles and thereby reduce glomerular filtration rate. Worsening renal function can be seen in 5% to 30% of patients treated with these agents; the risks are significantly higher in patients with more severe heart failure and in those with bilateral renal artery stenosis. Hyperkalemia may also occur, even in the

absence of declining renal function. At least 5% to 10% of patients treated with ACE inhibitors develop a dry, nonproductive cough. This probably results from the inhibition of bradykinin metabolism and resolves with cessation of the drug. Less than 1% of patients develop angioedema when they are treated with ACE inhibitors. This can be life-threatening and precludes further use of the drug. Both the efficacy and side effect profile of ACE inhibitors are affected by volume status, and careful monitoring of volume and appropriate diuretic dosing are important. Volume overload will blunt the therapeutic effects of ACE inhibitors, and whereas dietary sodium restriction may enhance the response to ACE inhibitors, volume depletion will exaggerate their hypotensive effects.

Angiotensin Receptor Blocking Agents. ARBs differ from ACE inhibitors in that they inhibit the binding of angiotensin to its receptor rather than block its production. Theoretically, ARBs should be more effective at inhibiting the renin-angiotensin-aldosterone system because they block angiotensin produced by both ACE and non-ACE pathways; however, clinical trials of ARB therapy in heart failure have not demonstrated consistent superiority over ACE inhibitors. A meta-analysis of 17 trials comprising more than 12,000 patients demonstrated that ARBs were not superior to ACE inhibitors in reducing morbidity or mortality of patients with heart failure, although they appeared to be beneficial in patients who are not already taking ACE inhibitors. The results of the Candesartan in Heart Failure Assessment of Reduction in Mortality and Morbidity (CHARM) trials have shed more light on this subject. These studies revealed that in patients with class II–IV heart failure and left ventricular ejection fraction of 40% or lower, treatment with the ARB candesartan resulted in clinically important reductions in mortality and hospitalization for heart failure. Importantly, the benefit was seen in patients who were intolerant of ACE inhibitors. Furthermore, in patients who were already receiving an optimal dose of an ACE inhibitor, the addition of candesartan produced additive clinical benefit.

ARBs have a risk of hypotension, renal dysfunction, and hyperkalemia similar to that of ACE inhibitors, and combination ARB and ACE inhibitor therapy is associated with an increased incidence of these adverse effects. The risk of angioedema appears to be decreased with ARBs compared with ACE inhibitors. In addition, because ARBs do not affect the kinin system, the incidence of cough is significantly less than that with ACE inhibitors. In general, ARBs are not yet considered first-line therapy for heart failure; however, they are a reasonable alternative in patients who are intolerant of ACE inhibitors because of the development of a persistent cough or angioedema and should be considered additive therapy in patients with persistent heart failure symptoms despite ACE inhibitor use.

β -Adrenergic Blocking Agents. The recent understanding of heart failure not only as a hemodynamic syndrome related to left ventricular systolic dysfunction but as a state of adverse neurohormone-mediated remodeling

TABLE 58-6 Oral Agents Commonly Used in the Treatment of Heart Failure

Class and Examples	Starting Dose	Target or Maximum Dose	Adverse Effects (by Class)
Nitrovasodilators			
Isosorbide mononitrate (Imdur)	30 mg qd	120 mg qd	Headache; nitrate tolerance with continuous use
Isosorbide dinitrate	10 mg tid	30 mg tid	
Direct-Acting Vasodilators			
Hydralazine (Apresoline)	10 mg qid	100 mg qid	Reflex tachycardia, lupus-like syndrome
Angiotensin-Converting Enzyme Inhibitors			
Captopril (Capoten)	6.25 mg tid	50 mg tid	Hypotension, cough, rash, angioedema, hyperkalemia
Enalapril (Vasotec)	2.5 mg bid	20 mg bid	
Lisinopril (Zestril, Prinivil)	2.5 mg qd	40 mg qd	Renal dysfunction (especially in patients with bilateral renal artery stenosis)
Ramipril (Altace)	2.5 mg qd	10 mg qd	
Quinapril (Accupril)	10 mg bid	40 mg qd	
Fosinopril (Monopril)	10 mg qd	40 mg qd	
Trandolapril (Mavik)	0.5 mg qd	8 mg qd	
Angiotensin Receptor Blockers			
Losartan (Cozaar)	50 mg qd	100 mg qd	Hyperkalemia
Candesartan (Atacand)	4 mg qd	32 mg qd	Renal dysfunction (especially in patients with bilateral renal artery stenosis)
Valsartan (Diovan)	80 mg qd	320 mg qd	
β-Adrenergic Blocking Agents			
Carvedilol (Coreg)	3.125 mg bid	25 mg bid	Bradycardia, hypotension, bronchospasm May worsen heart failure during initiation and titration
Metoprolol (Toprol XL)	25 mg qd	200 mg qd	
Bisoprolol (Zebeta)	1.25 mg qd	10 mg qd	
Inotropic Agents			
Digoxin (Lanoxin)	0.125 mg qd	Serum digoxin level: 0.5-0.8 ng/mL	Nausea, bradycardia, heart block, ventricular tachyarrhythmias
Calcium Channel Blockers*			
Amlodipine (Norvasc)	2.5 mg qd	10 mg qd	Amlodipine: pedal edema Verapamil and diltiazem: bradycardia, worsened systolic heart failure
Verapamil (Calan, Verelan)	120 mg qd	480 mg qd	
Diltiazem (Cardizem, Dilacor)	120 mg qd	540 mg qd	

*Calcium channel blockers should not be routinely used for the treatment of systolic heart failure. Although amlodipine is safe in this setting, verapamil and diltiazem may worsen systolic heart failure, and their use is limited to the treatment of diastolic heart failure.

has prompted extensive investigation into the use of beta-blocking agents in the treatment of heart failure. Basic studies have shown that these agents can inhibit the adverse effects of norepinephrine on the myocardium and result in upregulation of cardiac β -adrenergic receptors. The long-term administration of these agents is associated with a reversal of left ventricular remodeling, resulting in a decrease in left ventricular volume and an increase in ejection fraction with concomitant improvement in hemodynamics.

Large clinical trials encompassing more than 10,000 patients have demonstrated that these effects translate into significant clinical benefit. Although the enrollment criteria and the specific beta-blocking agent used varied among the trials, they all included patients with systolic heart failure (left ventricular ejection fraction of <35% to 45%) who were already being treated with a regimen of an ACE inhibitor and a diuretic, with or without digoxin. In sum, these trials demonstrated an approximately 35% reduction in mortality and 40% reduction in hospitalization due to heart failure in patients treated with beta-blocking agents. In addition, treatment with beta blockers reduces symptoms of heart failure and improves exercise capacity, although these effects may not be evident for several weeks or months after initiation of treatment (Fig. 58-4).

FIGURE 58-4 The effect of beta blocker therapy on clinical endpoints in patients with heart failure. Data from trials using metoprolol, carvedilol, bucindolol, and nebivolol. **A**, All-cause mortality; **B**, hospitalization for heart failure; **C**, combination of A and B; **D**, improved NYHA class; **E**, deteriorated NYHA class; **F**, left ventricular ejection fraction (LVEF). LVEF was measured after at least 5 months of therapy and reflects an unweighted mean increase of 29% with beta blocker therapy. (Modified from Lechat P, Packer M, Chalon S, et al: Clinical effects of beta-adrenergic blockade in chronic heart failure: a meta-analysis of double-blind, placebo-controlled, randomized trials. *Circulation* 98: 1184-1191, 1998.)

Three beta-blocking agents are currently approved by the Food and Drug Administration for the treatment of systolic heart failure: metoprolol, carvedilol, and bisoprolol. Metoprolol and bisoprolol are β_1 receptor specific; carvedilol inhibits the β_1 , β_2 , and α_1 receptors and has both vasodilative and antioxidant properties. The absolute magnitude of benefit is similar with these agents, and current trial data are inadequate to support use of one agent over another. Beta blocker therapy for heart failure should be initiated at lower doses than is routinely used for the treatment of hypertension or angina and gradually titrated upward to doses that have demonstrated benefit in clinical trials (see [Table 58-6](#)).

Use of beta-blocking agents can be associated with significant adverse effects in patients with heart failure. The renal hemodynamic effect of these agents may result in volume retention, which in combination with their negative inotropic effect may cause an initial worsening of heart failure symptoms. This adverse effect is more common in patients who are volume overloaded before beta blocker therapy and usually responds to an increase in diuretic dose. Hypotension is frequently seen after the initiation of beta blockers and may limit use of these agents. This effect is more pronounced with carvedilol because of its peripheral vasodilating effects and can usually be managed with a reduction in dose or changing to a β_1 receptor-specific agent. Other frequent side effects include fatigue and bradycardia, both of which can usually be managed with reduction of the dose of beta blocker or discontinuation of other atrioventricular nodal blocking agents (e.g., digoxin). Given the strength of the data supporting their use, beta blockers should be administered to all patients with systolic heart failure who do not have a contraindication to their use. Nonetheless, beta blockers should be avoided in patients with decompensated heart failure, symptomatic hypotension, or significant resting bradycardia or heart block in the absence of a permanent pacemaker.

Inotropic Agents

Digoxin. Digoxin is a cardiac glycoside and, as such, is a selective inhibitor of the membrane-bound Na^+/K^+ -ATPase. The binding of digoxin to this enzyme results in increased intracellular calcium with a resultant augmentation of myocardial contractility. In general, the overall effect on global left ventricular systolic function is relatively small, with an average absolute increase in ejection fraction of 1% to 2%. Digoxin also affects the cardiac conduction system through increases in vagal tone and decreases in sympathetic tone. This results in decreased automaticity of the atria and atrioventricular nodal tissues and prolongation of the refractory period and reduction in conduction velocity of the atrioventricular node. The net result is a slowing of the atrial rate and blockade of the atrioventricular node.

Several clinical trials have evaluated the role of digoxin in the treatment of patients with heart failure. The Prospective Randomized Study Of Ventricular Failure and Efficacy of Digoxin (PROVED) and the Randomized Assessment of Digoxin on Inhibitors of Angiotensin-Converting Enzyme (RADIANCE) trials studied the

effects of withdrawal of digoxin from clinically stable patients with class II or class III heart failure and systolic dysfunction. They found that withdrawal of digoxin was associated with a significant worsening of heart failure symptoms and deterioration of functional capacity. The Digitalis Investigation Group (DIG) trial evaluated the effect of starting digoxin in patients with systolic heart failure who were already receiving therapy with diuretics and ACE inhibitors. In this trial, digoxin use was associated with a decrease in the risk of hospitalization for heart failure but no change in overall mortality. Thus, digoxin can no longer be considered a first-line therapy for patients with heart failure; however, it appears useful in patients who remain symptomatic despite therapy with other agents. In this setting, the serum digoxin level should be maintained at 0.5 to 0.8 ng/mL; higher doses may be associated with adverse outcomes.

Digoxin may also be useful in the control of supraventricular arrhythmias in patients with depressed left ventricular systolic function. When it is used in this setting, digoxin may be given as an initial load (0.25 mg orally or intravenously every 8 hours for 24 hours) followed by a single daily dose of 0.125 mg or 0.25 mg. When it is used for the treatment of heart failure, there is little value in a loading dose, and once-daily dosing is appropriate. Digoxin is excreted unchanged by the kidney, and its dose must be adjusted in the setting of renal failure. It has a relatively narrow therapeutic window, and intermittent monitoring of its serum level is required. Higher serum digoxin levels (>2.0 ng/mL) are associated with an increased risk of toxic side effects ([Table 58-7](#)), especially in the presence of hypokalemia or hypomagnesemia. Mild digoxin toxicity (ectopic beats, first-degree atrioventricular block, gastrointestinal symptoms) may only require withholding of the drug. More severe toxicity (profound bradycardia, high-degree atrioventricular block, ventricular tachyarrhythmias) requires administration of digoxin-specific antibodies. Hemodialysis is ineffective for the treatment of digoxin toxicity.

Dopamine. Dopamine is the immediate metabolic precursor of epinephrine and norepinephrine. It is an endogenous catecholamine that functions as an essential neurotransmitter and is involved in the central regulation of movement and in the regulation of the cardiovascular system. Exogenously administered dopamine does not

TABLE 58-7 Signs and Symptoms of Digoxin Toxicity

Nausea, vomiting, abdominal pain
Anorexia
Fatigue, malaise
Confusion, delirium

First-, second-, or third-degree heart block
Excessively low ventricular rate in atrial fibrillation
Paroxysmal atrial tachycardia (classically with associated heart block)
Premature ventricular depolarizations
Ventricular tachycardia

cross the blood-brain barrier, and thus its effects are predominantly cardiovascular. The cardiovascular response to dopamine infusion is mediated by dopaminergic, β -adrenergic, and α -adrenergic receptors. At low doses (1 to 2 $\mu\text{g/kg/min}$), dopamine binds to dopaminergic receptors in the renal, mesenteric, and peripheral vasculature, stimulating a rise in intracellular cyclic adenosine monophosphate (cAMP) and inducing vasodilation in these beds. Although it produces a mild fall in systemic vascular resistance, its main effect is to increase glomerular filtration rate, renal blood flow, and renal sodium excretion, thereby augmenting urine output. At intermediate doses (2 to 5 $\mu\text{g/kg/min}$), dopamine induces the release of norepinephrine from sympathetic nerve terminals in the heart and directly stimulates cardiac β_1 -adrenergic receptors. This results in positive inotropic and chronotropic effects, augmenting cardiac output and causing tachycardia. Although intermediate-dose dopamine may be associated with increased systolic blood pressure, the systemic vascular resistance is usually unchanged because of renal and splanchnic vasodilation. At high doses of dopamine (5 to 15 $\mu\text{g/kg/min}$), α -adrenergic stimulation occurs, resulting in generalized vasoconstriction. A further rise in systolic blood pressure results; however, this occurs in association with an increase in systemic vascular resistance, which may suppress left ventricular systolic function because of the increase in afterload. In addition, at high doses, the α -adrenergic effects overcome the vasodilative effects in the renal and splanchnic vessels, and renal blood flow and urine output may decline.

The varied hemodynamic effects of dopamine make it a potentially useful agent for the treatment of heart failure in a variety of clinical settings. In the patient with congestion and oliguria but with adequate blood pressure, low-dose dopamine increases renal blood flow, thereby improving renal function, and augments urine output, thereby decreasing ventricular filling pressures. In the patient with cardiogenic shock, higher-dose dopamine is useful to maintain an adequate blood pressure. When the higher doses are used, patients must be monitored closely for signs of worsening heart failure; placement of a pulmonary arterial catheter is helpful in this regard. Although the increased systemic vascular resistance may be partially offset by the increase in cardiac contractility, in many patients, the ventricular filling pressures rise as a result of increased afterload. In addition, the venoconstricting effects augment venous return, thereby increasing ventricular preload. For these reasons, dopamine is not routinely used alone for inotropic support of the failing heart. Rather, for the treatment of patients with congestive heart failure, dopamine is often combined with another inotrope (e.g., dobutamine) or vasodilator (e.g., nitroprusside).

Although dopamine may have beneficial effects in some patients with congestive heart failure, there are few data to suggest an improvement in long-term outcomes. The use of dopamine is often limited by the development of tachycardia, which may precipitate ischemia in patients with coronary artery disease. Both supraventricular and ventricular arrhythmias may occur. In addition, dopamine may cause nausea, vomiting, and headaches

and may precipitate myocardial ischemia. Marked vasoconstriction may result in digital gangrene, especially in patients with peripheral vascular disease, and ischemic skin necrosis may occur at sites of cutaneous infiltration.

Dobutamine. Dobutamine is a synthetic catecholamine that acts by direct stimulation of α - and β -adrenergic receptors and is available as a racemic mixture of its (+) and (–) stereoisomers. The (–) isomer is a potent α_1 receptor agonist and a relatively weak β_1 receptor agonist. The (+) isomer is a potent β_1 and β_2 receptor agonist and an α_1 receptor antagonist. The net effect is relatively selective β_1 receptor stimulation, resulting in augmentation of contractility and increased cardiac output (see Fig. 58-2). In contrast to the hemodynamic effects of dopamine, the inotropic effect of dobutamine is associated with relatively little increase in heart rate and with a modest reduction in left ventricular filling pressure and peripheral resistance. The latter effect results from β_2 receptor-mediated vasodilation. Dobutamine does not bind to dopamine receptors; thus, it does not result in renal or splanchnic vasodilation. Nonetheless, renal blood flow may increase as a reflection of increased cardiac output.

The hemodynamic effects of dobutamine make it an ideal agent for the treatment of decompensated heart failure, either alone or in combination with other inotropic or vasodilating agents. Dobutamine is usually started at a dose of 2.5 $\mu\text{g/kg/min}$ and up-titrated in increments of 2.5 $\mu\text{g/kg/min}$ as needed until an adequate therapeutic effect is obtained, adverse effects occur, or the maximum therapeutic dose is reached (15 to 20 $\mu\text{g/kg/min}$). Patients with more advanced heart failure may have a greater degree of β -receptor downregulation and require higher initial doses of dobutamine. Patients receiving chronic beta blocker therapy may initially have relatively little inotropic response to dobutamine but a moderate vasopressor response resulting from the unmasking of α_1 -adrenergic vasoconstriction in the presence of β -receptor blockade.

If an adequate therapeutic response is not achieved despite maximal doses of dobutamine, a second agent should be added. For patients with increased ventricular filling pressures and adequate systolic blood pressure, the addition of a diuretic and a vasodilator (such as nitroprusside) should be considered. Alternatively, a phosphodiesterase inhibitor such as milrinone (see later) may be of value in this setting by further augmenting cardiac output and vasodilation. Patients with congestive heart failure associated with hypotension may require the addition of a vasopressor (i.e., high-dose dopamine) to augment blood pressure and to allow effective diuresis.

Dobutamine has proved an effective agent in the management of hospitalized patients with congestive heart failure. Intermittent administration of dobutamine to outpatients with severe heart failure has been associated with increased risk of death and should be avoided. Continuous infusions of dobutamine are usually well tolerated for up to several days, although tolerance may develop and limit the efficacy of longer term infusion. Dobutamine administration is occasionally limited by the

development of excess tachycardia; however, it is not uncommon to see a slight fall in the heart rate after dobutamine infusion as a result of withdrawal of sympathetic tone as the patient's hemodynamic status improves. Patients with a prior history of hypertension may have a marked hypertensive response to dobutamine; those with volume depletion may become hypotensive as a result of mild vasodilation. Like dopamine, dobutamine may precipitate atrial and ventricular arrhythmias and may aggravate myocardial ischemia.

Phosphodiesterase Inhibitors. Phosphodiesterase (PDE) is a membrane-bound enzyme that breaks down cAMP. It exists in several forms; PDE type 3 is the predominant isoform in cardiovascular tissue. Milrinone and amrinone inhibit this enzyme and thereby result in increased cytosolic cAMP. This in turn results in increased myocardial contractility and augmentation of cardiac output. In the vasculature, these agents are potent vasodilators and venodilators, resulting in reductions in systemic and pulmonary vascular resistance (afterload) and in right- and left-sided filling pressures (preload).

The mixed hemodynamic effects of PDE inhibitors distinguish them from other inotropes or vasodilators. Compared with dobutamine, milrinone produces a greater reduction in systemic vascular resistance for a given increase in cardiac output. Similarly, compared with nitroprusside, milrinone produces a greater increase in cardiac output for a given reduction in systemic vascular resistance (Fig. 58-5). Thus, PDE inhibitors may be useful for the management of patients with decompensated heart failure that is characterized by reduced cardiac output, elevated systemic vascular resistance, and elevated filling pressures. PDE inhibitors also have antiplatelet effects and cause dilation of epicardial coronary arteries and bypass grafts. These properties, combined with the previously noted reductions in pulmonary arterial pressure and pulmonary vascular resistance, have

given these agents an important role in the hemodynamic support of patients after cardiac surgery.

Amrinone (now renamed inamrinone) is less selective for the PDE3 isoenzyme, has a longer elimination half-life (2 to 3 hours vs. 30 to 60 minutes), and is approximately 10-fold less potent than milrinone. In addition, it has been associated with significant thrombocytopenia in 10% of patients in whom it is administered. For these reasons, amrinone has fallen out of favor and milrinone has become the PDE inhibitor of choice for the management of decompensated heart failure. Milrinone is given as an initial loading dose (50 $\mu\text{g/kg}$ over 10 minutes) followed by a continuous infusion (0.25 to 1.0 $\mu\text{g/kg/min}$). It is excreted predominantly by the kidney; in patients with renal failure, a 50% reduction in the infusion rate is required. Titration may be limited by the development of tachycardia and arrhythmias, both of which are mediated by the increase in cAMP. Because of the potent vasodilative properties of PDE inhibitors, they should be used with care in patients who have normal or low vascular resistance or filling pressures. These patients may be intolerant of the vasodilation, and marked hypotension may result.

Clinical trials have demonstrated the efficacy of intravenous milrinone in improving hemodynamics and reducing symptoms in hospitalized patients with decompensated heart failure. However, a mortality benefit has not been demonstrated, and when milrinone is administered routinely to patients with less-severe congestive heart failure (i.e., no evidence of end-organ hypoperfusion), it does not appear to offer benefit over usual treatment with ACE inhibitors and diuretics.

Other Agents

Natriuretic Peptides

Natriuretic peptides are naturally occurring peptides that are produced in low levels in the normal heart. Atrial natriuretic peptide (ANP) is produced in the atria, whereas brain natriuretic peptide (BNP; originally isolated from porcine brain tissue) is produced in the ventricles. In patients with heart failure, both ANP and BNP are secreted at high levels in response to increased intracardiac pressure and volume. These peptides act through a receptor-mediated guanosine monophosphate pathway in vascular smooth muscle cells and are degraded by neutral endopeptidase. They have potent balanced vasodilating actions resulting in decreased ventricular preload and afterload. In the kidney, these peptides cause vasodilation of the afferent arteriole, thereby increasing glomerular filtration rate, and inhibit sodium reabsorption in the renal collecting ducts and aldosterone secretion by the adrenal glands, thereby resulting in natriuresis and diuresis.

Nesiritide is a recombinant peptide that is identical to endogenous BNP and has both vasodilatory and natriuretic properties. In addition, it antagonizes the renin-angiotensin-aldosterone system. When it is administered to patients with heart failure, nesiritide reduces right atrial and pulmonary capillary wedge pressures, decreases systemic vascular resistance, increases cardiac output, and

FIGURE 58-5 ■ The relative effects of varying doses of nitroprusside (Ntp), dobutamine (Dob), and milrinone (Mil) on the peak positive change in pressure per change in time (dP/dt) and systemic vascular resistance (SVR). (Modified from Colucci WS, Wright RF, Jaski BE, et al: Milrinone and dobutamine in severe heart failure: differing hemodynamic effects and individual patient responsiveness. *Circulation* 73:11175–183, 1986.)

produces diuresis and natriuresis. Clinical studies have demonstrated persistent hemodynamic effects of prolonged (24- to 48-hour) infusions and improvements in clinical status that may be greater than those seen with intravenous nitroglycerin. Nesiritide is usually given as an initial bolus of 2 µg/kg followed by an infusion of 0.01 µg/kg/min. Its hemodynamic effects are apparent within 15 minutes and persist for up to 4 hours after discontinuation of the infusion. Nesiritide does not aggravate arrhythmias and has no toxic metabolites; however, significant and prolonged hypotension can occur with this agent and is the most common limiting factor. Furthermore, several recent meta-analyses have suggested an increased risk of death and worsened renal function after administration of nesiritide to patients with acutely decompensated heart failure. Thus, the use of nesiritide should be limited to the treatment of decompensated congestive heart failure characterized by volume overload and increased filling pressures in patients who are intolerant of inotropic agents and resistant to usual diuretics.

APPROACH TO THE MANAGEMENT OF HEART FAILURE

Initial Approach and Clinical Assessment

The treatment of heart failure is dependent on its recognition. Because heart failure may manifest in a variety of ways, the clinician must maintain a high index of suspicion, especially in the patient with a prior history of heart failure or with risk factors for the development of heart failure. Acute heart failure usually manifests dramatically with signs and symptoms of pulmonary and systemic congestion, at times associated with evidence of hypoperfusion (Table 58-8). In this setting, the clinical examination is usually striking and the diagnosis is rarely overlooked. Conversely, chronic heart failure may have a more indolent course, and the associated dyspnea, fatigue, and edema may be mistaken for other noncardiac conditions.

TABLE 58-8 Signs and Symptoms of Heart Failure

Evidence of Congestion	Evidence of Hypoperfusion
Symptoms	
Orthopnea	Fatigue, weakness
Dyspnea on exertion	Confusion
Paroxysmal nocturnal dyspnea	Symptomatic hypotension
Anorexia, nausea	
Signs	
Pulmonary rales	Cool extremities
Elevated jugular venous pressure	Mottled extremities
Hepatojugular reflux	Narrowed pulse pressure
Edema	Worsening renal insufficiency
Ascites	Progressive hyponatremia
Loud S ₃	Cheyne-Stokes respirations

In addition, the physical examination of patients with chronic heart failure may be somewhat misleading in that they often have clear lung fields despite having significantly elevated filling pressures.

The initial evaluation of the patient with heart failure should include an assessment of the disease severity. The most common classification in this regard is that devised by the New York Heart Association (see Table 58-2), which categorizes patients with symptomatic heart failure on the basis of their functional level. A broader classification scheme has recently been proposed by the American College of Cardiology/American Heart Association and includes patients with structurally normal hearts but at risk for development of heart failure (stage A), those with asymptomatic structural heart disease (stage B), those with overt heart failure (stage C), and those with severe heart failure that requires specialized care such as mechanical assistance or transplantation (stage D). Although the functional class may vary over time, these classifications remain useful because they provide an objective measure by which to follow disease progression and response to therapy. The choice of specific therapies is, in part, additionally dependent on disease severity. Patients with severe decompensated heart failure require the rapid administration of intravenous pharmacologic therapy to reduce pulmonary congestion, to augment perfusion of vital organs, and to attain hemodynamic stability. Conversely, patients with chronic compensated heart failure can frequently be treated with oral medications with the goal of controlling symptoms, improving functional capacity, and reducing long-term mortality.

In addition to the initiation of pharmacologic therapy, the initial approach to the care of the patient with heart failure should always include a thorough evaluation of the cause of heart failure and a careful search for aggravating or precipitating factors (Table 58-9). Although the history and physical examination may provide clues to the underlying cardiac abnormality, a formal assessment of cardiac function by echocardiography should be performed in all patients with new or significantly worsened heart failure. This test permits identification and characterization of pericardial, myocardial, and valvular disease and allows the quantification of left ventricular systolic and diastolic function. Initial laboratory evaluation should also include a chest radiograph (to assess cardiac size, pulmonary

congestion, and structural intrathoracic abnormalities), electrocardiogram (to evaluate for evidence of ischemic heart disease or ventricular hypertrophy), complete blood count, electrolyte values, thyroid function tests, and assessment of renal function.

All patients with heart failure should be counseled about lifestyle modifications that may help alleviate their symptoms. This includes moderate sodium restriction (≤ 2 g sodium daily); compliance with treatment regimens; and avoidance of alcohol, cigarettes, and nonsteroidal anti-inflammatory agents. Most heart failure patients do not require fluid restriction, but close monitoring of weight is essential for the early recognition of volume retention.

Pharmacologic Treatment of Chronic Compensated Systolic Heart Failure

Patients with chronic compensated heart failure represent a spectrum of patients ranging from those with asymptomatic left ventricular dysfunction to those with previously decompensated heart failure who have responded to medical therapy. The goals of treatment in this population include maintenance of a symptom-free state, improvement in functional capacity, prevention of decompensation, and reduction of mortality. Several individual classes of medications have proven efficacy in this regard (Table 58-10), although in general, most patients with systolic heart failure require multidrug therapy.

All patients with left ventricular systolic dysfunction should receive treatment with an ACE inhibitor because these agents improve mortality of patients with all classes of heart failure and delay the onset of symptoms in patients with asymptomatic left ventricular dysfunction. Therapy should be initiated at low doses and slowly titrated upward if it is tolerated (i.e., systolic blood pressure >90 mm Hg, no symptoms of hypotension) to doses that have been proved efficacious in randomized trials (see Table 58-6). Renal function should be monitored closely, especially in patients with concomitant vascular disease. Other vasodilators should be considered in patients with symptomatic heart failure who are unable to tolerate ACE inhibitors because of side effects. Whereas ARBs should not be used as first-line therapy for heart failure, they are the preferred agents for patients who develop cough with ACE inhibitors. Patients who develop progressive renal insufficiency or hyperkalemia

with ACE inhibitors are equally likely to develop these complications with ARBs; these agents should not be used in this setting. The combination of hydralazine and nitrates is a less effective regimen than ACE inhibitors but is a reasonable alternative in patients who are intolerant of these agents or ARBs.

All patients with class II-IV heart failure should also receive a beta blocker because these agents provide a marked mortality benefit. Care must be taken to ensure that patients are hemodynamically stable and near euvolemic before beta blocker therapy is started because initiation of beta blockade may be associated with orthostatic hypotension and worsening of heart failure symptoms. These agents should always be started at low doses (see Table 58-6), titrated very slowly (increasing dose every 2 weeks), and avoided in patients who recently required intravenous diuretics or inotropic agents. They should also be avoided in patients with a heart rate below 60 beats per minute, systolic blood pressure of less than 100 mm Hg, or evidence of atrioventricular block, and they should be used with care in patients with bronchospastic lung disease. Most patients with heart failure who receive beta blocker therapy should be concomitantly treated with diuretics, especially those patients with current or recent volume retention. If heart failure symptoms worsen after beta blockers are started, diuretic therapy should be initiated or increased; this often allows for continued beta blocker use. Clinical trials suggest that beta blocker therapy can be safely initiated in patients who are hospitalized for heart failure, providing they do not require intravenous inotropic support, the drug is started at a low dose, and there is careful assessment before further up-titration. It is generally preferable to initiate ACE inhibitor therapy before beta blocker therapy because ACE inhibitors result in rapid relief of symptoms and may facilitate the initiation of beta blockade.

Patients with symptoms or signs of congestion may respond to afterload-reducing therapy alone; however, most require the addition of a diuretic. Loop diuretics such as furosemide are preferred because they are more effective than thiazide diuretics, especially in patients with renal insufficiency (serum creatinine concentration >2.5 mg/dL). If volume overload persists despite upward titration of the loop diuretic, addition of a thiazide (e.g., metolazone 2.5 mg orally given 30 minutes before the loop diuretic) should be considered and provides effective combination therapy. This combination can lead to profound potassium and magnesium wasting and requires

TABLE 58-10 Beneficial Effects of Oral Pharmacotherapy for Chronic Heart Failure

Medication	Improves Mortality	Improves Symptoms	Reduces Recurrent Heart Failure	Heart Failure Class for Which Treatment Is Indicated
Angiotensin-converting enzyme inhibitors	Yes	Yes	Yes	Class I-IV*
Beta blockers	Yes	Yes	Yes	Class II-IV
Hydralazine	Yes	Yes	No	Class II-IV†
Spironolactone	Yes	Yes	No	Class III-IV
Diuretics	No	Yes	No	Class II-IV
Digoxin	No	Yes	Yes	Class II-IV

*Also indicated in patients with asymptomatic left ventricular systolic dysfunction.

†Not a first-line drug but should be considered in patients who are intolerant of angiotensin-converting enzyme inhibitors.

close monitoring of serum electrolytes. Spironolactone (25 to 50 mg daily) should be added to the regimen of patients with class III-IV heart failure because it provides a mortality benefit in this setting.

Digoxin should be considered in any patient who continues to have symptomatic heart failure despite treatment with an ACE inhibitor and beta blocker. Although this agent has not demonstrated a mortality benefit in any class of heart failure, when it is used as part of a multidrug regimen, it is useful for controlling symptoms and reducing hospital admissions. It may be particularly beneficial in patients with atrial fibrillation, in whom improved heart rate control may lead to symptomatic improvement.

Treatment of Decompensated Systolic Heart Failure

Patients with chronic systolic heart failure may have periods of relative stability interrupted by periods of decompensation. These periods of decompensation may be precipitated by medication noncompliance, dietary indiscretion (i.e., excessive sodium or water intake), or progression of the underlying myopathic process. The patient often reports a gradual worsening of symptoms or progressive weight gain during the course of several days, although the clinical presentation may appear relatively acute.

Patients with decompensated heart failure may present with hemodynamic instability and usually have evidence of systemic and pulmonary congestion with or without evidence of decreased organ perfusion. Although pulmonary arterial catheterization is sometimes necessary to precisely define the hemodynamic derangement, many patients with decompensated heart failure can be adequately evaluated on the basis of their clinical history and physical examination findings, specifically whether they have evidence of pulmonary or systemic congestion or organ hypoperfusion. Congestion may be evidenced by an elevation in the jugular venous pressure, the presence of pulmonary rales, or peripheral edema. These patients are usually dyspneic with minimal exertion or even at rest and often report increased orthopnea and paroxysmal nocturnal dyspnea. Hypoperfusion may be manifested as cold extremities, mottled skin, cyanosis, mental obtundation, or declining renal function. Measurement of the pulse pressure (the difference between the systolic and diastolic blood pressures) may be helpful; in patients with heart failure, the pulse pressure narrows. A pulse pressure of less than 25% of the systolic blood pressure generally correlates with a cardiac index of less than 2.2 liters/min/m².

For patients in whom the hemodynamic profile needs to be more accurately defined or in whom initial therapy yields suboptimal results, direct measurement of hemodynamic parameters should be performed through the insertion of a Swan-Ganz catheter (Table 58-11). The information thus obtained may be used to guide the selection and titration of specific pharmacologic therapy. Such tailored therapy should be undertaken with the goal of manipulating medications to achieve optimal hemodynamics, including a right atrial pressure of less than 8 mm

TABLE 58-11 Potential Indications for Invasive Hemodynamic Assessment in Patients with Heart Failure

Assessment of volume status when clinical assessment is uncertain
Distinguishing heart failure from other causes of dyspnea (e.g., pulmonary disease)
Assessment of hemodynamic response to vasoactive medications
Guidance in achieving ideal hemodynamic goals (tailored therapy)
Assessment of filling pressure in patients with persistent symptoms of heart failure despite aggressive medical therapy
Determination of appropriate therapy in patients with persistent congestion and progressive renal insufficiency after diuretic therapy
Assessment of pulmonary vascular resistance during evaluation for cardiac transplantation
Perioperative monitoring of volume status in patients with severe left ventricular dysfunction undergoing prolonged procedures associated with significant volume shifts or in patients with decompensated heart failure on preoperative assessment

Hg, a pulmonary capillary wedge pressure of less than 18 mm Hg, a cardiac index above 2.2 liters/min/m², and a systemic vascular resistance of 800 to 1200 dynes/sec/cm⁻⁵.

Taken together, these findings can be used to classify the severity of hemodynamic impairment of a patient presenting with decompensated heart failure and to help make decisions about appropriate initial therapy (Fig. 58-6). Patients with left ventricular dysfunction who are well compensated generally have acceptable filling pressures and adequate cardiac outputs, do not have congestion, and appear well perfused. These patients require chronic heart failure therapy as outlined earlier for symptom control and mortality reduction. Patients with decompensated heart failure who have evidence of congestion without hypoperfusion have elevated filling pressures with adequate cardiac output. These patients may simply be volume overloaded and require aggressive diuresis. If the blood pressure is adequate, addition of a vasodilator (e.g., ACE inhibitor) may further augment cardiac output and facilitate diuresis. Patients with signs of hypoperfusion but without congestion have acceptable filling pressures but decreased cardiac output. Therapy in this setting should be guided by the patient's blood pressure; patients with hypotension require inotropic therapy, whereas patients with adequate systolic blood pressure (>100 mm Hg) should receive vasodilators with or without inotropic agents to augment cardiac output. These patients do not generally require aggressive diuresis and, in fact, may be volume depleted and require gentle hydration. Patients with evidence of both congestion and hypoperfusion have both elevated filling pressures and decreased cardiac output and are the most difficult to manage. These patients frequently require combination therapy with inotropic agents, intravenous vasodilator therapy, and use of diuretics. Invasive hemodynamic monitoring may be most helpful in guiding

therapy in this group of patients, especially in patients with associated hypotension.

Various intravenous agents are available for use in the treatment of patients with decompensated heart failure (Table 58-12). Initial management should be guided by

FIGURE 58-6 ■ An approach to treatment of acute or decompensated heart failure. ACE, Angiotensin-converting enzyme; CHF, congestive heart failure.

the patient's specific hemodynamic alterations. In patients with severe hypotension leading to organ dysfunction, stabilization of the blood pressure is the primary goal. Dopamine at moderate to high doses has traditionally been used as the initial drug of choice in this setting; however, recent data suggest that in the management of cardiogenic shock, treatment with norepinephrine is associated with fewer arrhythmias and lower mortality than is treatment with dopamine. In general, vasoconstrictors should be avoided in patients with left ventricular dysfunction because they may lead to further depression of cardiac output. In patients with adequate blood pressure whose predominant manifestation of heart failure is congestion, initial treatment with nitroprusside (or nitroglycerin or nesiritide) is usually effective. In patients whose predominant manifestation is hypoperfusion, dobutamine, milrinone, nitroprusside, or nesiritide may be effective. Most patients with decompensated heart failure also require administration of intravenous diuretics and careful management of fluid balance.

Treatment of Diastolic Heart Failure

In contrast to the treatment of systolic heart failure, the treatment of diastolic heart failure has not been extensively studied, and there are no large-scale randomized trials by which to guide therapeutic recommendations. The general approach is aimed at treatment of the underlying cause and the relief of symptoms with medications that intuitively should reduce diastolic pressures. The impairment in diastolic filling results in an increase in atrial pressure early in the course of this disease, with resultant pulmonary and venous congestion. Diuretics therefore play an important role in the management of this syndrome and help control congestive symptoms. Care must be taken to avoid overdiuresis because these patients depend on an elevated filling pressure to maintain stroke volume. Calcium channel blockers (verapamil or diltiazem) and beta blockers slow the heart rate,

TABLE 58-12 Intravenous Agents Used in the Treatment of Decompensated Heart Failure

Medication	Hemodynamic Effects	Potential Adverse Clinical Effects
Dopamine		
Low dose	Splanchnic vasodilation, ↑GFR, ↑urine output	Myocardial ischemia, arrhythmias
Intermediate dose	↑HR, ↑contractility, ↑CO, ↑BP, ↑/–SVR	Myocardial ischemia, arrhythmias, ↑CHF, worsened renal function
High dose	↑HR, ↑↑contractility, ↑↑BP, ↑↑SVR, ↓CO, ↑PCW, ↓/–GFR	Myocardial ischemia, arrhythmias
Dobutamine	↑HR, ↑↑contractility, ↑CO, ↑/–BP, ↓SVR, ↓PCW	Myocardial ischemia, arrhythmias
Isoproterenol	↑↑HR, ↑contractility, ↑CO, ↓SVR	Myocardial ischemia
Epinephrine	↑HR, ↑contractility, ↑SVR, ↑BP	Myocardial ischemia, arrhythmias, ↑CHF, worsened renal function
Norepinephrine	↑HR, ↑contractility, ↑↑SVR, ↑↑BP	Myocardial ischemia, arrhythmias, ↑CHF, worsened renal function
Milrinone	↑Contractility, ↑↑CO, ↓↓SVR, ↓PVR, ↓↓PCW	Myocardial ischemia, arrhythmias, hypotension
Nitroprusside	↑↑CO, ↓↓SVR, ↓PVR, ↓↓PCW	Hypotension, cyanide and thiocyanate toxicity
Nitroglycerin	No effect on contractility ↑CO, ↓SVR, ↓PVR, ↓↓PCW, coronary vasodilation	Hypotension, headache, nitrate tolerance
Nesiritide	No effect on contractility ↑CO, ↓SVR, ↓↓PCW, ↑GFR Natriuresis, diuresis	Hypotension

prolong diastole, and allow increased time for left ventricular filling. In addition, these agents may improve diastolic ventricular function (i.e., decrease left ventricular stiffness and improve left ventricular relaxation) by improvement in calcium homeostasis. In patients who are intolerant of these medications or who have continued symptoms despite their use, ACE inhibitors may offer further benefit. Data suggest that ventricular hypertrophy is associated with stimulation of the renin-angiotensin system and that chronic activation of this system results in fluid retention as well as myocardial fibrosis and increased ventricular stiffness. Inhibition of this system with ACE inhibitors or ARBs may therefore offer further treatment of the underlying pathophysiologic changes characteristic of diastolic heart failure. Inotropic therapy, including digoxin, should be avoided in diastolic heart failure; these agents are unlikely to be beneficial in the face of preserved systolic function and may worsen diastolic function, leading to further elevation of filling pressures and progressive heart failure.

Other therapies for diastolic heart failure are aimed at treating the underlying cause of the dysfunction and correcting associated abnormalities that may worsen this dysfunction. Hypertension is the most common condition that predisposes to diastolic heart failure. Small studies suggest that it is the extent of hypertension control, not the specific antihypertensive agent used, that results in improved diastolic function. Patients with secondary causes of hypertension (e.g., renal artery stenosis, hyperadrenalism) should undergo definitive therapy when possible. Patients with coronary artery disease should be aggressively treated with antianginal therapy, and coronary revascularization should be performed when appropriate. Aortic stenosis should be surgically corrected when it is associated with diastolic heart failure, even in the absence of systolic dysfunction. Patients with diastolic heart failure are highly preload dependent and may experience acute decompensation if they develop atrial fibrillation. This occurs in part because of the loss of the active atrial contribution to left ventricular filling and in part because the increased heart rate associated with the development of atrial fibrillation shortens diastole and allows less time for left ventricular filling. All efforts should be made to restore and maintain sinus rhythm in these individuals.

Flash Pulmonary Edema

Decompensated heart failure that develops acutely in a previously asymptomatic or well-compensated patient is often the result of an abrupt change in cardiac structure or function (Table 58-13). The precipitous nature of the presentation of these patients accounts for the commonly used descriptive term *flash pulmonary edema*. In this setting, patients are often hemodynamically unstable and develop severe pulmonary congestion, although they frequently are not fluid overloaded. These patients are pharmacologically treated similarly to the decompensated patients described earlier; however, specific therapy should be guided by the underlying precipitating factor. Patients with ischemia precipitating acute heart failure frequently have severe coronary artery disease (i.e.,

TABLE 58-13 Precipitants of Flash Pulmonary Edema and Their Therapeutic Implications

Acute	Specific Therapeutic Considerations
Ischemia or infarction	Cardiac catheterization and revascularization
Hypertension	Intravenous vasodilators (nitroprusside, enalaprilat) with 25% reduction in mean arterial pressure as initial goal
Renal artery stenosis	Percutaneous renal artery revascularization
Aortic stenosis	Aortic valve replacement after initial stabilization with diuretics, $\pm$ vasopressors, $\pm$ inotropic agents
Acute aortic insufficiency (endocarditis, aortic dissection)	Aortic valve replacement after initial stabilization with vasodilators $\pm$ inotropic agents
Acute mitral regurgitation (ischemia, endocarditis, ruptured chordae)	Consider intra-aortic balloon pump for hemodynamic stabilization before coronary revascularization for ischemic mitral regurgitation or mitral valve replacement for structural mitral regurgitation
Supraventricular tachyarrhythmias	Rate control or electrical cardioversion

three-vessel or left main coronary artery disease) or have papillary muscle dysfunction resulting in acute mitral regurgitation (most common with disease of the right coronary artery). In addition to heart failure therapy as dictated by their clinical presentation, these patients should receive aggressive antianginal therapy with intravenous nitrates and antiplatelet agents (i.e., aspirin, heparin, $\pm$ IIb/IIIa inhibitors), and urgent cardiac catheterization and coronary revascularization should be considered. For patients with refractory heart failure and ischemia, intra-aortic balloon pump counterpulsation may be a beneficial adjuvant therapy while awaiting definitive revascularization.

Severe hypertension may precipitate acute heart failure. Classically, this occurs with hypertension associated with pheochromocytomas, renal artery stenosis, and alcohol or cocaine use, but it can be seen also in patients with preexisting heart failure who are noncompliant with medications or dietary sodium restriction. Appropriate therapy in this setting is dependent on blood pressure control. Intravenous antihypertensive agents (e.g., nitroprusside, enalaprilat) should be started with the goal of lowering the mean arterial pressure by 25% in the first several hours and reducing the systolic blood pressure below 160 mm Hg within the first 24 hours. Acute severe aortic insufficiency as occurs with endocarditis or aortic dissection should be managed with intravenous inotropic agents or vasodilators (depending on systemic blood pressure) while preparing for emergent surgical therapy. Acute mitral regurgitation often responds to vasodilator therapy but may require intra-aortic balloon pump counterpulsation for stabilization before valve replacement.

Perioperative Heart Failure

For various reasons, the incidence of heart failure is increased in the perioperative period. Many anesthetic agents have negative inotropic effects and can precipitate heart failure in patients with left ventricular systolic dysfunction, and the vasodilative effects of these agents may result in hypotension. Aggressive fluid resuscitation in this setting may lead to volume overload, elevated filling pressures, and pulmonary congestion. Similarly, appropriate replacement of blood products in the face of intraoperative blood loss may be poorly tolerated and may require the concomitant administration of diuretics. Mechanical ventilation produces beneficial hemodynamic effects in heart failure because of a reduction in venous return induced by the increased intrathoracic pressure. Conversely, the decrease in intrathoracic pressure associated with extubation may be followed by a sudden rise in preload and result in heart failure. Fluid that entered the extravascular space during the perioperative period reenters the vascular space several days postoperatively as patients begin to mobilize. This rise in circulating blood volume may similarly precipitate heart failure. These adverse effects are more likely to occur in patients with preexisting left ventricular dysfunction and in patients with overt heart failure preoperatively.

In the preoperative setting, the identification of decompensated heart failure is essential. The presence of pulmonary or systemic congestion or signs of hypoperfusion should prompt a thorough assessment of the patient's cardiac status, reevaluation of the patient's current therapy, and delay or cancellation of all but emergent procedures until the patient's status is stabilized. If the patient's ventricular function is not known, echocardiography should be performed to aid in determining the mechanism of heart failure and to guide appropriate therapy. In the postoperative period, heart failure may be mistaken for pneumonia, atelectasis, exacerbation of chronic obstructive pulmonary disease, or pulmonary embolism. Patients are often unable to communicate their symptoms to the treating physicians because of sedation and mechanical ventilation; thus, the physician's vigilance is essential. Identification of pulmonary rales, jugular venous distention, hepatojugular reflux, gallop rhythm, or peripheral edema should raise the concern of worsening heart failure, and close monitoring of the patient's weight and fluid balance should alert the physician to the possibility of volume overload.

In patients with more advanced heart failure (class III or IV) or with severely depressed left ventricular systolic function (<25%), placement of a pulmonary arterial catheter preoperatively should be strongly considered, especially for such patients who are undergoing prolonged procedures that are associated with significant fluid shifts. In patients with decompensated heart failure, placement of this catheter the day before surgery allows time for optimization of their hemodynamic status, thereby potentially decreasing their overall perioperative risk. Continued invasive hemodynamic monitoring for 24 to 48 hours after surgery may be appropriate in some patients.

Patients with chronic heart failure are often dependent on medications to maintain their hemodynamic stability,

and every effort should be made to continue these medications in the perioperative period. Although it may be appropriate to hold diuretics on the day of surgery, careful attention to volume status is obligatory postoperatively, and intravenous diuretics should be administered at the first signs of congestion. Beta blockers and ACE inhibitors should likewise be continued because the sudden withdrawal of these agents may result in neurohormonal activation and worsening of heart failure. Intravenous formulations may be substituted for many oral medications in patients who are unable to take oral agents postoperatively because of the nature of their surgery. However, well-compensated patients often tolerate withholding of their usual medications and can be managed for several days with intravenous diuretics and topical nitrates for preload reduction. If refractory congestion or signs of organ hypoperfusion develop, use of intravenous vasodilators or inotropes may become necessary. These agents may be transitioned to oral formulations as gut absorption improves. For patients who remain hemodynamically labile postoperatively, use of short-acting agents may be appropriate for several days; long-acting agents may be reinstituted when the volume shifts and hemodynamic derangements improve. Given the tenuous nature of these patients, it is often helpful to involve a cardiology consultant to help manage the complex hemodynamic changes that occur in the perioperative period.

SPECIAL CONSIDERATIONS

Off-Pump Coronary Artery Bypass
Minimally Invasive Cardiac Surgery
Robotic-Assisted Cardiac Surgery

Anesthesia was successfully demonstrated for the first time in 1846. Prior to that time, it was deemed impossible to perform major surgical procedures because of the associated pain and discomfort.¹ Anesthesia has been one the greatest catalysts in the evolution of surgery since the 1840s. The first successful cardiac surgical procedure occurred in 1902, when Hill closed a stab wound to the heart of a 13-year-old boy. Over the years, the anesthesiologist's role has evolved from mere drug administrator to being an integral partner in the perioperative management and support of the cardiac surgical patient. Today, transesophageal echocardiography (TEE) plays an essential role in the patient's intraoperative diagnosis, monitoring, and prognostication, with the anesthesiologist taking part in the surgical planning and decision making.² The discipline of cardiac anesthesia encompasses an ever-expanding body of knowledge. This chapter provides a brief overview of preoperative anesthetic evaluation and intraoperative anesthetic management for adult cardiac surgery.

PREOPERATIVE EVALUATION

The preoperative anesthetic evaluation of the cardiac surgical patient includes the following: (1) review of the events that led to the indication for cardiac surgery, (2) identification and optimization of risk factors that could lead to increased mortality and morbidity resulting from cardiac surgery, and (3) gathering of information relevant to selecting appropriate monitoring modalities and management techniques during surgery.

Indications for Cardiac Surgery

A detailed history should be obtained on the evolution of disease in question, with emphasis on current and past symptoms, previous need for hospitalization, and current functional capacity.

An important part of functional capacity assessment is the evaluation of limitation in the activities of daily living. Patients who can normally walk up a flight of stairs or a hill and do heavy work around the house (scrubbing floors, etc.) have a lower risk of cardiopulmonary complications associated with surgery.³

Identification and Optimization of Risk Factors

Higgins and colleagues⁴ performed a retrospective logistic regression on data from more than 5000 patients who underwent coronary artery bypass grafts and then prospectively applied the retrospectively identified risk factors to a group of more than 4000 patients. They found that 30-day mortality was predicted by the emergency of the procedure, preoperative serum creatinine of more than 168 mmol/L, left ventricular ejection fraction of less than 35%, preoperative hematocrit level of less than 35, age older than 70 years, chronic pulmonary disease, prior vascular surgery, reoperation, and mitral regurgitation. Emergency cases included transfers from the coronary care unit with unstable angina (48%), complications of percutaneous intervention (40%), and complications of routine cardiac catheterizations (12%). In addition to these risk factors, nonfatal morbidity was

predicted by diabetes mellitus, body weight of 65 kg or less, aortic stenosis, and cerebrovascular disease. Presence of these risk factors needs to be ascertained when obtaining preoperative history prior to cardiac surgery.

Several standardized scores can be used for assessing risk in the cardiac surgical population. In the 1980s, Parsonnet et al described a score useful for assessing risk of mortality related to cardiac surgery.⁵ This original model has been substituted in recent years by other models, including the European System for Cardiac Operative Risk Evaluation (euroSCORE) or the Society of Thoracic Surgeons risk calculator.⁶⁻¹⁰ Some of the factors associated with mortality during cardiac surgery are shown in Table 59-1. A recent study analyzed more than 29,000 patients undergoing elective cardiac surgery. In this study, an index that included patient age, creatinine levels, and ejection factors showed definitive association with mortality and the score was comparable to euroSCORE risk estimation.¹¹

Patients' current use of medications should be sought, and their dose and frequency noted. In general, all cardiovascular medications should be continued even on the day of surgery, except diuretics and angiotensin-converting enzyme inhibitors. Preoperative β -adrenergic blocker use has been associated with increased survival after coronary artery surgery.¹²

Of particular interest are anticoagulant and thrombolytic drugs, because they can cause increased bleeding in the perioperative period. Relevant information about anticoagulant use includes current as well as prior treatment with heparin or warfarin, along with dosage and time of the last dose, and history of heparin resistance or heparin-induced thrombocytopenia, use of warfarin with dosage, and time of the last dose.

Emergency patients may have received thrombolytics and/or inhibitors of platelet aggregation. Clopidogrel (Plavix) and ticlopidine (Ticlid) inhibit adenosine diphosphate (ADP)-induced platelet aggregation by irreversibly modifying platelet P2 receptors. Abciximab (ReoPro) is a monoclonal antibody fragment against glycoprotein (GP) IIb/IIIa receptor, which allows platelet binding to von Willebrand factor and fibrinogen. Abciximab is administered intravenously with an initial bolus of 0.25 mg/kg, followed by an infusion of 0.125 mcg/kg/min (up to 10 mcg/min) for 12 hours. After discontinuance of Abciximab, platelet function recovers gradually over the next 48 hours.^{13,14} Eptifibatide (Integrilin) is a

peptide inhibitor of GP IIb/IIIa receptor with an elimination half-life of 1 to 2 hours. After discontinuance, platelet function (as measured by bleeding time) recovers in 2 to 4 hours.¹⁵ Tirofiban (Aggrastat) is a peptidomimetic antagonist of GP IIb/IIIa receptor with an elimination half-life of about 2 hours; platelet function returns to normal within 4 to 8 hours after discontinuing the medication.^{16,17} Abciximab could prolong the activated clotting time (used for heparin effect monitoring) by 30 to 50 seconds, and a reduction in the dosage of heparin is necessary. Eptifibatide does not have a similar effect on activated clotting time.¹⁸

Information Relevant for Selecting Appropriate Monitoring Modalities and Management Techniques

In every cardiac surgical patient, contraindications to TEE have to be evaluated (e.g., esophageal disease or previous esophageal surgery). Furthermore, a history of cold agglutinin antibody may contraindicate hypothermic cardiopulmonary bypass (CPB), whereas a history of antiphospholipid syndrome will adversely affect measurement of activated clotting time while the patient is on CPB. The possibility of previous thoracic surgery or radiation, and the presence of a pacemaker or an implantable cardioverter/defibrillator, should also be evaluated.

Physical examination should be focused on assessing the airway, cardiovascular, and respiratory systems. The airway examination should include evaluation of dentition: any evidence of infection or abscess must be ruled out. Blood pressure should be measured on both arms, and any significant difference should raise suspicion of subclavian artery stenosis. The Allen test may be performed in case a radial artery harvest is being considered to provide a conduit, or invasive blood pressure monitoring on the radial artery is planned. Femoral pulsation should be palpated, and the presence of any peripheral vascular disease should be noted (this may make the placement of an intra-aortic balloon pump challenging). Carotid bruits should be listened for, and cardiac sounds should be auscultated. Hepatomegaly, jugular venous distention, and peripheral edema should also be noted.

Preoperative laboratory tests should include hematocrit, platelet count, coagulation parameters, electrolytes, serum creatinine, glucose, 12-lead electrocardiogram,

TABLE 59-1 Conditions Commonly Associated with Increased Mortality after Cardiac Surgery

Patient Related	Comorbidities	Disease Related	Surgery Related
Age (>60) Gender (female) Obesity	Extracardiac arteriopathy Diabetes mellitus Renal impairment	Recent myocardial infarction Left ventricular dysfunction Pulmonary hypertension	Previous cardiac surgery Urgent surgery Surgical procedure other than or associated with coronary artery bypass graft
Poor mobility	Dialysis	Cardiogenic shock	Surgery on the descending thoracic aorta
Critical preoperative state Poor functional capacity	Chronic lung disease Atrial fibrillation	Intra-aortic balloon pump Left main coronary artery disease	

and a chest radiograph. An echocardiogram, if obtained, provides not only information about preoperative ventricular and valve function and anatomy but also a baseline to which intraoperative TEE findings can be compared. The catheterization report should be reviewed for the distribution of coronary artery disease, ventricular systolic and diastolic dysfunction, valvular abnormalities, pulmonary hypertension, and intracardiac shunt.

INTRAOPERATIVE MANAGEMENT

Monitoring

The American Society of Anesthesiologists standards for basic anesthetic monitoring include electrocardiography, pulse oximetry, capnography, noninvasive blood pressure determination, and temperature monitoring.¹⁹

On surface electrocardiogram (ECG), ST-segment analysis should be continuously performed. In a classic study by London et al, patients were evaluated with a 12-lead ECG during noncardiac surgery, and ischemia was defined as either ST depression of at least 1 mm or elevation of at least 1.5 mm in a non-Q wave lead. In this study the sensitivity of the V5 lead alone for detection of ischemia was 75%; that of V5 and V4 combined was 90%; V5 and II 80%; and V5, V4, and II combined was 96%.²⁰ Use of the standard five-lead ECG system does not allow simultaneous monitoring of V5 and V4, and the most practical alternative is to monitor leads V5 and II, the latter of which is also the most useful for arrhythmia monitoring. When right-sided ischemia is of concern, the right shoulder electrode may be placed in the right precordial area, and then lead I becomes the right precordial lead (V₄R). Simultaneous monitoring of V5, II, and V₄R allows for the detection of virtually 100% of all

ischemic episodes that are detectable with a full 12-lead ECG.²¹

In addition to the noninvasive monitors, invasive monitors are routinely used in cardiac surgery (Fig. 59-1). An arterial line should be placed before or immediately after induction for continuous blood pressure monitoring and intermittent blood sampling. The radial artery is most commonly used, but the brachial, ulnar, axillary, femoral, and dorsalis pedis arteries are alternative sites of cannulation. If the internal mammary artery is to be used as a graft, the contralateral radial artery should be selected because of the theoretical concern of subclavian artery compression by the retractor during conduit harvest. If the surgery involves the takeoff of the innominate artery or the left subclavian artery, or if the radial artery is to be harvested as a conduit, the corresponding radial artery should not be used for an arterial line, and an alternative site should be sought. For an operation of the descending thoracic aorta, two arterial lines with one proximal to the proximal clamp and one distal to the distal clamp are recommended. The proximal arterial line (usually in the right radial artery) provides information about the perfusion pressure of the myocardium and the brain. The distal arterial line (usually a femoral artery line or, in the absence of a peripheral vascular disease, a dorsalis pedis line), in conjunction with an intrathecal catheter, allows the calculation of the perfusion pressure of the spinal cord.

A central venous line (CVL) is routinely used in cardiac surgery to allow for reliable administration of cardiovascular medications and heparin and to monitor central venous pressures. Whether the use of a pulmonary artery catheter (PAC) should be routine or selected on an individual basis in cardiac surgery is a matter of debate. In a prospective comparison of a CVL with a PAC in 1094 patients undergoing coronary artery surgery

FIGURE 59-1 ■ Monitoring. Parameters monitored during complex cardiac surgery include a multiple-lead electrocardiogram, intracranial pressure, pulmonary artery pressure, one or multiple arterial lines, pulse oxymetry, capnogram, and nasopharyngeal temperature.

(including the highest risk patients), Tuman and colleagues²² found that there was no difference in outcome. Similarly, Schwann and coworkers²³ reported that, in their experience with 2685 consecutive patients undergoing coronary artery bypass surgery, the use of a PAC was limited to 9% (2.4% unplanned—i.e., converted from a CVL) of the patients and predicted by ejection fraction, Society of Thoracic Surgeons risk score, intra-aortic balloon pump, congestive heart failure, re-do surgery, and New York Heart Association class IV. With such a selective use, their observed-to-expected ratio of mortality as compared with the Society of Thoracic Surgeons database was 0.73. Furthermore, the presence of a PAC has not been shown to influence anesthetic management during induction,²⁴ which is generally considered one of the higher risk periods during anesthesia. These studies suggest that the anesthesiologist should be highly selective when choosing cardiac surgery patients in whom to use a PAC. However, a PAC, unlike a CVL, can provide information about cardiac output, systemic and pulmonary vascular resistance, and mixed venous saturation, and some models allow for venous pacing of the heart. On the other hand, TEE may negate some of the potential advantages of a PAC over a CVL: cardiac output measured by TEE can be reliable and comparable with that measured by a PAC,²⁵ TEE-guided right and left ventricular oximetry may be feasible,²⁶ and pulmonary artery pressures can be estimated by TEE.²⁷

TEE has emerged as one of the most important tools in the planning and execution of cardiac surgical procedures. The American Society of Echocardiography and the Society of Cardiovascular Anesthesiologists have published guidelines for the comprehensive intraoperative TEE examination, a full discussion of which is beyond the scope of this chapter.²⁸ The impact of TEE on surgical decision making and clinical outcomes is well established.²⁹⁻³¹ Given this evidence and its safety profile,³² TEE is now routinely indicated as frequently useful in several clinical scenarios (Box 59-1). In addition to serving as a monitor of myocardial and valvular function, TEE is an invaluable guide for the placement of coronary sinus and intra-aortic catheters, for the delineation of the anatomy and pathology of valve lesions, and for before-and-after comparison of myocardial perfusion and function and valvular anatomy and function.³³ In addition, TEE may be used to assess the delivery of cardioplegia^{34,35} and to predict changes in regional myocardial function after coronary artery bypass.³⁶ In valve repair procedures, TEE is indispensable in assessing the presurgical severity as well as the immediate quality and result of repair.

Three-dimensional TEE imaging has gained significant clinical importance in terms of ability to reveal more accurate information than traditional methods to base clinical decisions on. Studies have shown TEE's superiority in determining aortic valve area in the context of assessing severity of aortic stenosis as well as mechanism, thereby impacting intraoperative clinical decisions regarding valve replacement. For aortic valve replacement, for example, multiple methods for valve area assessment are currently in practice. However, studies show that images obtained using three-dimensional

BOX 59-1 Indications for Transesophageal Echocardiography

Indications—Category I: Supported by strongest evidence or expert opinion; transesophageal echocardiography (TEE) is frequently useful in improving clinical outcomes in these settings and is often indicated, depending on individual circumstances (e.g., patient risk and practice setting).

- Intraoperative evaluation of acute, persistent, and life-threatening hemodynamic disturbances in which ventricular function and its determinants are uncertain and have not responded to treatment
- Intraoperative use in valve repair
- Intraoperative use in congenital heart surgery for most lesions requiring cardiopulmonary bypass
- Intraoperative use in repair of hypertrophic obstructive cardiomyopathy
- Intraoperative use for endocarditis when preoperative testing was inadequate or extension of infection to perivalvular tissue is suspected
- Preoperative use in unstable patients with suspected thoracic aortic aneurysms, dissection, or disruption who need to be evaluated quickly
- Intraoperative assessment of aortic valve function in repair of aortic dissections with possible aortic valve involvement
- Intraoperative evaluation of pericardial window procedures
- Use in intensive care unit for unstable patients with unexplained hemodynamic disturbances, suspected valve disease, or thromboembolic problems (if other tests or monitoring techniques have not confirmed the diagnosis or patients are too unstable to undergo other tests)

echocardiography are able to capture the elliptical shape of the left ventricular outflow tract (LVOT), complete with information regarding major and minor axes.³⁷ This allows more accurate planimetric assessment of the LVOT and, therefore, calculation of aortic valve area by continuity equation. In addition, short axis TEE views are helpful in interrogating cusp symmetry and origin of the aortic regurgitation jet. In planning the repair, it is important to know whether the jet is central, commissural, cuspal, or all along the coaptation line (Fig. 59-2).

The advent of three-dimensional echocardiographic data has also allowed precise assessment of complex structures such as heart valves without geometric assumptions (Figs. 59-3 and 59-4). Using multi-planar reformatting, orthogonal views can be extracted from volumetric echocardiographic data to make accurate linear measurements (Fig. 59-5). Quantitative analyses of valvular apparatus are particularly valuable in identifying indices of remodeling to establish the chronicity and severity of valvular pathology (e.g., mitral regurgitation). This helps in identifying patients who may be unsuitable candidates for repair procedure because of irreversible remodeling of valvular apparatus. Increasingly, echocardiographic assessment during cardiac surgery is evolving from a qualitative interrogation to a quantitative analysis including, but not limited to, quantification of regurgitation, linear dimensions, and stress patterns before and after repair.

In surgeries of the descending thoracic aorta, cerebrospinal fluid pressure (CSFP) may be measured with an intrathecal catheter. If such a catheter is placed, CSFP should be maintained at less than or equal to 10 cm H₂O, and cerebral spinal fluid (CSF) should be allowed to drain when CSFP is greater than 10 cm H₂O.³⁸ However, spinal cord perfusion depends not only on CSFP but also on the arterial pressure distal to the distal clamp, and maintenance of the distal arterial pressure may be just as important when using, for example, a partial bypass or a shunt. Whether monitoring of CSFP and drainage of CSF to maintain CSFP at less than 10 cm H₂O prevents paraplegia after descending thoracic aortic surgery is still under debate.³⁹

Choice of Anesthetic Agents

High-dose opioid anesthesia was developed in the late 1960s by Lowenstein and colleagues.⁴⁰ This technique

was based on the observation that patients on mechanical ventilation after cardiac surgery tolerated large dosages of morphine (0.5 to 3 mg/kg) for sedation and analgesia with minimal hemodynamic effects. Such large dosages were then tried as a component of anesthesia for cardiac surgery, with significant success.⁴¹ Opioids by themselves do not ensure amnesia, and they require supplementation with an amnesic such as a benzodiazepine or scopolamine. Synthetic opioids such as fentanyl (50 to 100 mg/kg) or sufentanil (5 to 10 mg/kg) provided similar hemodynamic effects, with the advantage that fluid retention often seen with high-dose morphine anesthesia did not occur with these agents. Although highly successful and popular in the 1980s and early 1990s, high-dose opioid anesthesia has gradually given way to a balanced anesthetic technique that involves a lower dosage of opioids, in conjunction with inhalational anesthetics and other intravenous adjuncts, that results in a faster onset and offset to facilitate early extubation and discharge from the intensive care unit (ICU).

There has been increasing evidence that inhalational agents precondition the heart, thus protecting it from subsequent ischemic episodes in a fashion analogous to that of ischemic preconditioning, whereby a brief period of ischemia protects the heart from subsequent prolonged ischemic episodes.⁴²⁻⁴⁴ Anesthetic preconditioning was initially described in an animal model, in which 0.75 minimum alveolar concentration of halothane attenuated ST-segment elevation after coronary artery occlusion.⁴⁵ The mechanism for this increased tolerance to ischemia is thought to occur in part via activation of adenosine triphosphate (ATP)-sensitive potassium channels on the cardiac myocyte.⁴⁶ This effect is independent of changes in systemic and coronary hemodynamics and persists despite discontinuation of the volatile anesthetic.⁴⁶ Some clinical trials have postulated that anesthetic preconditioning could occur in patients during coronary as well as valvular surgery,⁴⁷⁻⁴⁹ whereas others have failed to confirm it.⁵⁰⁻⁵² Currently, inhalational agents are the mainstay of anesthesia for cardiac surgery, and these are supplemented with muscle relaxants and a modest amount of opioids for analgesia.

FIGURE 59-2 ■ Three-dimensional color flow Doppler. Three-dimensional transesophageal echocardiographic image of a mitral regurgitation jet that extends throughout the coaptation line.

FIGURE 59-3 ■ Mitral valve open/closed. En face view of the mitral valve obtained with three-dimensional transesophageal echocardiography demonstrates the valve in a closed (A) and open position (B). The image can then be rotated to reveal valve anatomy as seen from the left ventricle (C).

FIGURE 59-4 ■ AP diameter. Three-dimensional echocardiographic imaging may allow for better visualization of heart anatomy and the changes it undergoes throughout the cardiac cycle. A three-dimensional reconstruction of the mitral valve and the changes it undergoes in its AP annular diameter is demonstrated here. AL, Anterolateral; AP, anteroposterior; PM, posteromedial.

FIGURE 59-5 ■ Multiplanar reformatting (MPR) of three-dimensional echocardiographic images can allow for more precise measurements by aligning orthogonal planes across structures of interest. In this case the planes are aligned so that the area and diameters of the mitral annulus (*bottom left*) can be measured.

Although the observation by Reiz and colleagues⁵³ in 1983 that isoflurane may cause coronary steal (a phenomenon in which coronary blood flow is diverted away from the collateral-dependent region of the myocardium) tended to discourage the use of the inhalational agent, subsequent investigators failed to duplicate the findings.⁵⁴⁻⁵⁶ The newer agents sevoflurane and desflurane do not cause coronary steal either.^{57,58} In addition, animal studies suggested that isoflurane may preferentially dilate large coronary arteries rather than arterioles (thus mimicking the effect of nitroglycerin⁵⁹) and normal coronary arterioles rather than arterioles from a collateral-dependent region of the myocardium.^{60,61}

Fast-track cardiac surgery (FTCS) refers to a multidisciplinary approach to providing care to cardiac surgical patients, with emphasis placed on early tracheal extubation (within 6 to 10 hours postoperatively) and expedited mobilization of the patient (with consequent reductions in ICU and hospital lengths of stay and cost).⁶² Factors that predict the success or failure of this approach (other than age) are intraoperative and postoperative clinical process variables, such as intraoperative inotrope use, intraoperative placement of an intra-aortic balloon pump, and postoperative atrial arrhythmias; thus, there is no need to preselect patients for FTCS, and everyone may be considered a potential candidate for early extubation.⁶² An important component of FTCS is an anesthetic technique that allows early extubation and mobilization of the patient.⁶³ Instead of a long-acting muscle relaxant (e.g., pancuronium), a shorter-acting agent (e.g., rocuronium, cisatracurium) may be used.⁶⁴⁻⁶⁶ Any residual blockade at the end of surgery or during the initiation of weaning may be reversed with an acetylcholinesterase inhibitor (e.g., neostigmine) in combination with an antimuscarinic agent. Instead of a high-dose opioid technique, a low- or moderate-dose opioid technique in combination with inhalational anesthetics may facilitate early tracheal extubation.⁶⁷ Hypothermia at the end of surgery should be prevented.⁶⁸ Although early extubation is favored, there is no benefit to pushing for tracheal extubation in the operating room.⁶⁹ The cost of extended operating room time and the risk of cardiorespiratory instability during the early postoperative period should also be considered. In both a retrospective review⁷⁰ and a prospective randomized controlled trial,⁷¹ it has been demonstrated that FTCS is not associated with any increase in hospital mortality or morbidity. Rather, the rate of nosocomial pneumonia may be decreased with FTCS.⁷⁰ The reintubation rate is not significantly different between FTCS and the conventional approach, and both ICU and hospital length of stay are decreased with FTCS. In response to concerns that FTCS may result in cost shifting rather than cost savings, Cheng and colleagues⁷² examined the resource use of both FTCS and conventional patients for a year after hospital discharge. Although insurance claims for outpatient visits were not significantly different at 3 months and 12 months, insurance claims and costs for inpatient care were significantly lower for the FTCS group. The savings in inpatient care were 68% at 3 months and about 50% at 1 year. Thus, FTCS may lead to savings during both the initial hospitalization for the surgery and the subsequent follow-up period.

Regional Anesthesia and Analgesia

The use of thoracic epidural anesthesia (TEA) as a supplement to general anesthesia carries several potential advantages. TEA attenuates the sympathetic stress response to surgical stimulation, reduces heart rate and myocardial oxygen consumption, and decreases the release of troponin T.^{73,74} Postoperatively, TEA provides superior analgesia, thus enabling early extubation and vigorous pulmonary toilet and reducing the incidence of lower respiratory tract infections as compared with conventional intravenous analgesia.^{75,76} Despite these advantages, TEA has not been widely accepted for cardiac surgery because of concern for a potential epidural hematoma in patients that are heparinized for CPB. The true incidence of an epidural hematoma in cardiac surgery is not known, and this complication is infrequent in cardiac surgical settings.⁷⁷ A mathematical model suggests that the risk ranges from 1:150,000 to 1:1500.⁷⁸

Recently, with the advent of off-pump, minimally invasive cardiac surgery, several European groups have reported using TEA as the sole anesthetic modality without endotracheal intubation in patients undergoing coronary artery bypass surgery^{79,80} and aortic valve replacement.⁸¹ The authors state that potential advantages of avoiding general anesthesia might include the use of the patient's mental status as a monitor of cerebral ischemia and achievement of truly FTCS. In a study of this modality by Karagoz and colleagues,⁷⁹ 8 out of 137 patients went home the day of surgery, and 58 of these 137 did not require any ICU stay, for an overall mean hospitalization of 1 day. However, 39 out of the 137 patients had a pneumothorax, and 4 of them had to be converted to general anesthesia because of pneumothorax-related respiratory difficulties. Potential disadvantages of an awake technique in cardiac surgery include the stress response of an awake patient to surgical maneuvers such as sternotomy, and a delay in surgical progress.⁸²

TEA for cardiac surgery has not yet found acceptance in the United States mainly because of the risk of epidural hematomas, its medicolegal implications, and limited evidence of an outcome benefit.

Intraoperative Blood Glucose Control

Acute and chronic hyperglycemia increase the risk of myocardial ischemic injury through several mechanisms.⁸³ Hyperglycemia decreases coronary collateral blood flow, causes endothelial dysfunction, and compromises the salutary effect of ischemic preconditioning or anesthetic-induced pharmacologic preconditioning.^{84,85} Among oral hypoglycemic agents, sulfonylureas and other insulin secretagogues impair K_{ATP} channel activation and may therefore hinder ischemic or pharmacologic preconditioning. Such agents should be discontinued for 24 to 48 hours before surgery.⁸³

Hyperglycemia occurs frequently in patients with and without diabetes during cardiac surgery.⁸⁶ Intraoperative hyperglycemia is associated with a higher morbidity and mortality in patients undergoing cardiac surgery,⁸⁷⁻⁸⁹ which might suggest that tight intraoperative glycemic control would reduce postoperative complications.

Although postoperative strict blood glucose control with insulin has been shown to definitely decrease mortality and morbidity in patients after cardiac surgery,^{90,91} similar results have not been obtained when the control was initiated during the surgery.⁹² Furnary et al⁹³ performed a prospective study of almost 2500 consecutive diabetic patients undergoing cardiac surgery who were randomized to receive either intensive insulin therapy with continuous infusion to maintain blood glucose at less than 200 mg/dL or intermittent subcutaneous insulin injections on a sliding scale. Blood glucose was better controlled with intravenous infusion (85% of patients with blood glucose <200 mg/dL on postoperative day 1, with a mean level of 199 ± 1.4 mg/dL) than with subcutaneous injections (47% of patients with <200 mg/dL, with a mean level of 241 ± 1.9 mg/dL). The incidence of deep sternal wound infection was significantly reduced in the infusion group (0.8% vs. 2.0%, $P = 0.01$) and approached that of the nondiabetic patients. Mortality was likewise reduced with intensive insulin therapy (3.0% vs. 6.1%, $P = 0.03$). In a retrospective review of 3554 diabetic patients from the same group,⁹⁴ mortality was directly related to postoperative mean glucose; it was demonstrated to be 0.9% for those with a level of less than 150 mg/dL, 1.3% for those with 150 to 175 mg/dL, 2.3% for those with 175 to 200 mg/dL, 4.1% for those with 200 to 225 mg/dL, 6.0% for those with 225 to 250 mg/dL, and 14.5% for those with greater than 250 mg/dL.

Intensive insulin therapy to tightly control blood glucose should not be employed intraoperatively only but should be extended into the postoperative period in the ICU. In a prospective study of 1548 patients in the surgical ICU (about two thirds of whom had been through cardiac surgery), intensive insulin therapy to maintain a glucose level between 80 and 110 mg/dL was associated with a lower mortality as compared with conventional therapy to maintain a glucose level between 180 and 200 mg/dL (4.6% vs. 8.0%, $P < 0.04$).⁹⁰ However, in a more recent randomized controlled study,⁹⁵ tight glucose control (81 to 108 mg/dL) was associated with a higher mortality in comparison to liberal control (<180 mg/dL). This increased mortality was not entirely explained by hypoglycemia; it is thought to be because of increased variability in glucose concentrations in the tight control group.

For perioperative glycemic control in diabetic patients, Martinez and colleagues⁹⁶ have suggested that all patients, even those not on an oral diet, require a basal insulin infusion and that exogenous insulin must be given for insulin-deficient patients. Their recommendation was to maintain the blood glucose level at less than 180 mg/mL at all times (between 80 and 110 mg/mL in the ICU), to avoid oral hypoglycemic agents until the patients are on an oral diet, to provide basal insulin to patients who are insulin deficient,⁹⁷ and to implement a hypoglycemia-prevention protocol.⁹⁶

Acid-Base Management during Hypothermia

As the temperature decreases, the solubility of a gas increases and the neutral pH of water (at which $[H^+] =$

$[OH^-]$) also increases. As a result of this, even though the total content of CO_2 does not vary, its partial pressure decreases during hypothermia. The two approaches for acid-base management during hypothermic CPB are pH-stat and alpha-stat management. With pH-stat management, the clinical objective is to maintain a pH of 7.4 at the patient's true core temperature. Blood gases and pH are measured with a correction for temperature. To maintain a pH of 7.4 at hypothermic temperatures usually requires the addition of exogenous CO_2 to maintain a temperature-corrected $PaCO_2$ of 35 to 40 mm Hg. The objective of alpha-stat management is to maintain electroneutrality. With this approach, blood gases and pH are measured without temperature correction (i.e., as if the patient's temperature were always 37°C) and maintained at a $PaCO_2$ of 40 mm Hg and a pH of 7.4. The actual pH is allowed to vary with body temperature.

With pH-stat measurement, the addition of CO_2 corrects the hypothermia-induced leftward shift of the oxyhemoglobin dissociation curve and may improve oxygen delivery to the tissues. On the other hand, because the cerebral blood flow response to CO_2 is preserved during hypothermia, pH-stat management may lead to excessive cerebral blood flow and interference with cerebral autoregulation and flow-metabolism coupling.^{98,99} However, clinical neuropsychologic outcome has not been shown to differ between pH-stat and alpha-stat management.¹⁰⁰

Anticoagulation for Cardiopulmonary Bypass

Heparin was first isolated in 1918 from liver tissue, and its name is derived from the Greek word *hepar*, meaning "liver."¹⁰¹ Heparin sulfate, which is currently produced from either porcine gut or bovine lung, is used to mimic the natural role of heparan sulfate on the vascular endothelial surface. Heparin, although it has no anticoagulant effect by itself, complexes with and enhances the activity of antithrombin (AT) in irreversibly neutralizing thrombin and activated factor X. Heparin also increases the activity of heparin cofactor II to inhibit the action of thrombin.¹⁰² What constitutes a safe and effective level of heparinization for CPB has not been established, in part because of the inconsistent relationship between heparin dosage, plasma heparin concentration, and clinical effect (as measured by the activated clotting time [ACT]), and in part because the ACT is a nonspecific test affected not only by heparin but also by platelets and temperature.¹⁰³ Most currently accepted heparin regimens use an initial dosage of 250 to 400 IU/kg to maintain an ACT of greater than 400 to 480 seconds.¹⁰⁴ However, animal studies suggest that reduced heparin administration to maintain an ACT between 250 and 300 seconds may be just as adequate.¹⁰⁵

Administration of heparin may be associated with hyperkalemia¹⁰⁶ or hypotension; the latter may be as a result of heparin-induced production of nitric oxide.¹⁰⁷ Heparin resistance may be defined as the failure of 500 IU/kg of heparin to prolong the ACT to 480 seconds or greater.¹⁰⁸ Factors that predict heparin resistance include AT levels of 60% or less, preoperative

subcutaneous or intravenous heparin therapy, platelet count of 300,000 or more per milliliter, and age of 65 years or older.¹⁰⁹ AT levels may be low because of reduced synthesis caused by genetic defects or from acquired causes such as liver disease, oral contraceptive use, and disseminated intravascular coagulation. Furthermore, increased consumption of AT may be related to disseminated intravascular coagulation, extensive deep vein thrombosis, sepsis, or preeclampsia; or from concomitant use of heparin, nitroglycerin, or the chemotherapeutic agent L-asparaginase. Treatment of heparin resistance with increasingly higher dosages of heparin is intended to maximally bind all available AT and sometimes may be effective. Alternatively, the patient may receive fresh frozen plasma¹¹⁰ or AT concentrate. In vivo recovery of AT activity is about 1.4% per unit of administered AT concentrate,¹¹¹ and the therapeutic goal should be to maintain AT activity at more than 80%.

Heparin-induced thrombocytopenia (HIT) is a potential complication of heparin treatment. This condition is also known as heparin-associated immune thrombocytopenia, heparin-associated thrombocytopenia and thrombosis (HITT), and white clot syndrome.^{112,113} HIT is divided into two types. Type I HIT is characterized by platelet activation and mild thrombocytopenia occurring within the first 2 days of treatment. Type II HIT is a serious immune-mediated disorder that can progress to arterial or venous thrombosis. It presents usually within 4 to 10 days after heparin treatment,¹¹² but it may also occur after heparin has been withdrawn¹¹⁴ or rapidly after the start of heparin administration (median time, 10.5 hours for early-onset HIT).¹¹⁵

Unfractionated heparin (UFH), which is used for anticoagulation during CPB, is associated with a higher risk for HIT than low-molecular-weight heparin (LMWH).¹¹⁶ The incidence of clinically significant HIT was low in cardiac surgery with CPB,¹¹⁷ although the incidence of heparin-dependent immunoglobulin G (IgG) antibodies was 15% to 20% in patients undergoing cardiac surgery.¹¹⁸ Patients who have a history of HIT but are negative for HIT antibodies at the time of surgery, and who require CPB, have been successfully anticoagulated with a brief course of treatment with UFH, without complications.¹¹⁹ If perioperative HIT is diagnosed, all exposure to heparin should be immediately ceased, and argatroban, lepirudin, or bivalirudin should be considered for prophylactic therapy of thrombosis until the platelet count has recovered.

After separation from CPB, heparin activity is neutralized by the administration of protamine, a compound isolated from fish sperm. To reverse the effects of heparin, protamine is given in a ratio of 1 mg of protamine per 100 UI of heparin. The use of additional doses during CPB and the variable half-life of heparin (30 to 150 min) may make dose calculations more difficult.¹²⁰ Automated heparin-protamine titration assays can also be used to calculate the protamine dose needed for reversal. Just as incomplete reversal of heparinization may lead to excessive post-bypass bleeding, excessive protamine can decrease both platelet number and function,¹²¹ can prolong ACT,¹²² and can reduce the effect of thrombin.¹²³ Determining whether a prolonged ACT after an adequate dosage of protamine indicates incomplete

heparin reversal or excessive protamine may require measurement of the thrombin time and the heparinase-ACT.

An important differential diagnosis of bleeding after CPB despite a seemingly adequate dose of protamine is heparin rebound. Besides binding to AT, heparin also binds nonspecifically to other plasma and PLT-derived proteins, as well as to endothelial cells. The affinity of heparin through this nonspecific binding process is much less than its affinity to AT. After its administration, heparin binds to AT and to other plasma proteins. When protamine is administered, it binds and displaces a large proportion of heparin from its plasma protein binding sites. The resulting heparin/protamine complexes are then cleared from the circulation by the reticuloendothelial system. Heparin rebound occurs because not all of the heparin is bound to and cleared by protamine. Instead, a proportion remains nonspecifically bound to plasma proteins and provides a reservoir of heparin that dissociates over time and produces an anticoagulant effect when it binds to AT.¹²⁴ Postoperative protamine infusion eliminates heparin rebound.¹²⁵

Five types of protamine-related adverse reactions have been recognized. First, rapid administration of protamine (>5 mg/min) may at times induce the release of histamine from mast cells and thus cause systemic hypotension.¹²⁶ Second, protamine may act like an antigen and initiate an IgG- or IgE-mediated anaphylactic reaction, especially in diabetic patients who take daily subcutaneous protamine-containing insulin preparations,¹²⁷⁻¹²⁹ and possibly in those with a fish allergy or those who have just had a vasectomy.¹³⁰ Third, protamine-heparin complexes may activate the complement system, thereby leading to an anaphylactoid reaction.^{131,132} Fourth, protamine-heparin-mediated complement activation may lead to thromboxane A₂ generation, precipitating catastrophic pulmonary hypertension¹³³; this is in contrast to the low systemic and pulmonary pressures seen in classic anaphylactoid reactions. In a pig model, this reaction was preventable by prior administration of indomethacin or a thromboxane A₂ receptor antagonist.¹³⁴ Last, fulminant noncardiogenic pulmonary edema and systemic anasarca have been reported 15 minutes to more than 1 hour after the administration of protamine.¹³⁰ Treatment of a protamine reaction is mainly supportive, and various agents (e.g., diphenhydramine, steroids) and hemodynamic support have been suggested. In a patient with a history of prior adverse reaction to protamine, it should be determined whether the reaction was immunologically mediated. Levels of IgG, IgE, thromboxane, and C5a at the time of the reaction, if available, may be useful, but a skin test or enzyme-linked immunosorbent assay has not been found to be useful.¹²⁶ When the cause of the reaction is uncertain, some people advocate pretreatment of the patient with steroids and histamine receptor blockers and slowing the administration of protamine. If a true immunologically mediated protamine reaction were to occur, it would be best to avoid it. Protamine alternatives that are being tested include recombinant platelet factor 4,¹³⁵ hexadimethrine,¹³⁶ heparinase,¹³⁷ and a heparin removal device that uses a venovenous circuit with a poly-L-lysine-agarose surface.¹³⁸

Use of Antifibrinolytics

Despite adequate heparinization, CPB is usually accompanied by a low-level activation of coagulation and fibrinolysis,¹³⁹ which leads to the consumption of coagulation factors and increased postoperative bleeding. Three antifibrinolytics in common use are ε-aminocaproic acid (EACA), tranexamic acid (TA), and aprotinin. EACA and TA are synthetic analogs of the amino acid lysine and competitively block the lysine binding sites between plasmin and fibrin or fibrinogen. They reduce fibrinolysis and, by reducing fibrin split products, indirectly prevent platelet dysfunction. No uniform dosage regimen has been established for either EACA or TA. For EACA, a plasma level of 130 mg/mL is needed for the complete inhibition of fibrinolysis,¹⁴⁰ and dosage regimens include three doses of 10 g (before the incision, on pump, and after bypass) or a weight-based initial loading of 150 mg/kg followed by an infusion of at least 15 mg/kg/hr. For TA, Horrow and colleagues¹⁴¹ recommend a 10-mg/kg load followed by an infusion of 1 mg/kg/hr, but other regimens have also been published. Both EACA and TA are renally eliminated. TA has been found to be as effective as, or more effective than, EACA for reducing blood loss, but both were better than placebo.^{142,143} In patients requiring deep hypothermic circulatory arrest (DHCA), there have been reports of fatal thrombosis in association with EACA use.¹⁴⁴

Aprotinin is a serine protease inhibitor that inhibits plasmin, trypsin, kallikrein, and bradykinin-kinin. The activity of aprotinin is measured in kallikrein-inhibiting units (KIU), and 1 mg of aprotinin is equal to 7140 KIU. In addition to inhibiting fibrinolysis, aprotinin may reduce the consumption of coagulation factors and the activation of mediators of inflammation. Aprotinin is at least as effective as TA or EACA for reducing perioperative blood loss, but it is much more costly.¹⁴² High-dose (also referred to as full-dose) aprotinin involves a loading dose of 2,000,000 KIU (280 mg) followed by an infusion dose of 500,000 KIU/hr, with an additional 2,000,000 KIU in the pump. Because of concern about the cost and side effects of the medication, a low-dose (half-dose) regimen, which consisted of a loading dose of 1,000,000 KIU (280 mg) followed by an infusion dose of 250,000 KIU/hr, with an additional 2,000,000 KIU in the pump, has been tried and appears to be equally effective.¹⁴⁵⁻¹⁴⁷ Aprotinin is cleared renally and may cause thrombotic sludging in the renal tubules, thus leading to a risk-adjusted increase in serum creatinine level and renal dysfunction but not renal failure.^{148,149} A nonrandomized retrospective study by Mangano and coworkers demonstrated that aprotinin was associated with a doubled risk of renal failure requiring dialysis.¹⁵⁰ However, other studies showed that aprotinin was not associated with clinically significant renal dysfunction.^{151,152} Aprotinin has been used safely even in patients with chronic renal failure or preexisting renal dysfunction.^{153,154} In one report, renal dysfunction and thrombotic complications were noted with aprotinin use in patients requiring DHCA,¹⁵⁵ but other authors found aprotinin to be safe even with DHCA.¹⁵⁶⁻¹⁵⁸ Although nonrandomized retrospective studies have shown that aprotinin was

associated with higher mortality, myocardial infarction, and stroke,^{148,150,159} another meta-analysis of 138 randomized controlled trials did not demonstrate any significant risks for mortality, stroke, or myocardial infarction with aprotinin use.¹⁴⁹ A multicenter randomized blinded trial with a head-to-head comparison of aprotinin, ε-aminocaproic acid, and tranexamic acid concluded that although aprotinin was a more effective hemostatic agent, it was associated with increased 30-day hospital mortality.¹⁶⁰ As a result of these findings, aprotinin has been withdrawn from the market in several countries, including the United States. Because aprotinin is isolated from bovine-lung mast cells, there is a risk of allergic reactions, with the incidence of anaphylaxis reported to be less than 0.6% on initial exposure but up to 5% with reexposure within 6 months,¹⁶¹ although the incidence falls rapidly to 1.9% in the 6- to 12-month period, and to 0.4% in the > 12-month period.¹⁶¹

Cerebral Protection

Central nervous system injury is a frequent complication of cardiac surgery. A large multicenter study found an overall incidence of 6.1% of adverse cerebral outcomes.¹⁶² Perioperative stroke worsens prognosis in patients who have undergone cardiac surgery, increasing mortality at 1 year up to 30% when compared to patients without stroke.¹⁶³

Brain injury associated with cardiac surgery is multifactorial, and the main role of the anesthesiologist is to provide supportive measures to prevent it. Brain oxygen supply and demand balance must be maintained. This involves prevention and aggressive management of hypotension with vasoactive medications or volume expansion. Adequate gas exchange and oxygenation must be ensured. Depth of anesthesia should be controlled, to diminish brain metabolism, hence augmenting tolerance to ischemia. Hyperglycemia and high body temperature should be avoided because both can increase neurologic damage.

Deep hypothermic circulatory arrest (DHCA) is an important management strategy for acquiring a bloodless surgical field in certain types of surgery, particularly in aortic arch reconstruction. Techniques that have been used to ameliorate ischemic injury of the brain during DHCA include selective cannulation and perfusion of cerebral vessels, retrograde cerebral perfusion, pharmacologic brain protection, and the achievement of deep hypothermia. At normothermia, roughly half of the oxygen consumed is used to maintain cellular integrity ("basal" cerebral metabolic rate [CMRO_2]), and the other half is used to maintain electrical activity ("functional" CMRO_2).¹⁶⁴ Hypothermia has a greater effect on the basal CMRO_2 than on the functional CMRO_2 .¹⁶⁵ The electroencephalogram (EEG) becomes isoelectric at 18° C, and below this temperature, any further reduction in CMRO_2 is from a decrease in basal CMRO_2 . Barbiturates, which reduce functional CMRO_2 without having much effect on basal CMRO_2 , do not produce any additional metabolic suppression under conditions of deep hypothermia (15° C), and they are not likely to be of benefit.¹⁶⁶ On the other hand, barbiturates may be of benefit for ameliorating the effects of temporary focal

ischemia (e.g., from an air embolus on normothermic bypass) by the suppression of functional CMRO₂.

Ischemic injury from DHCA may be temporally divided into four phases.^{167,168} The first phase is marked by failure in energy production and membrane depolarization. After ischemic depolarization occurs, detrimental neuroexcitatory transmitters such as glutamate are released. With the restoration of blood flow, the third phase ensues, marked by an increased release of oxygen free radicals and subsequent tissue damage. In the fourth phase, ischemia may also trigger apoptosis or programmed cell death over the ensuing weeks. Inhalational anesthetics lower the critical cerebral blood flow to a level below which the majority of patients develop ischemic EEG changes.^{169,170} At normothermia, the critical cerebral blood flow is 10 mL/100 g/min for isoflurane, 11.5 mL/100 g/min for sevoflurane, 15 mL/100 g/min for enflurane, and 20 mL/100 g/min for halothane. This metabolic suppression effect of inhalational agents amounts to delaying the first phase of ischemic injury. In addition, isoflurane may inhibit excitotoxicity from the accumulation of glutamate during the second phase of ischemic injury. Isoflurane has been shown to reduce the release of glutamate during ischemia¹⁷¹ and may also be an antagonist of glutamate receptors, thereby diminishing deleterious calcium influx.¹⁷² Because of its effect on the first two phases of ischemic injury, isoflurane may buy time before irreversible neuronal damage sets in. However, in aortic surgery settings where DHCA is used, anesthetics have not been demonstrated to be of benefit. Similarly, although various other pharmacologic modalities (e.g., diuretics, steroids, calcium channel blockers) have been used, none has been demonstrated to be of benefit in DHCA.

Hemodynamic Support on Separation from Cardiopulmonary Bypass

Separating a patient from CPB may be considered a form of cardiopulmonary resuscitation, and thus it should start with the confirmation of a patent airway (usually with an endotracheal tube) and the reestablishment of ventilation. For support of the circulation, the anesthesiologist needs to continually assess and treat alterations in preload, afterload, contractility, rate, and rhythm. Furthermore, the metabolic parameters that affect myocardial function, such as pH, electrolytes (especially potassium, calcium, and magnesium), oxygen-carrying capacity (hemoglobin), and temperature, have to be controlled. In addition, the anesthesiologist needs to maintain constant communication with the surgical team, because certain maneuvers may mechanically affect myocardial function. TEE assessment of the adequacy of the surgery (e.g., valvular anatomy and function) and the patient's tolerance of separation from CPB also needs to be communicated to the surgeon.

Usually, epicardial pacing wires are placed, and the pacing function is tested before separation. A rhythm that preserves the atrial augmentation of ventricular preload is preferred (e.g., sinus rhythm, atrioventricular sequential pacing). If the pump flow is set at an adequate cardiac output, the vascular tone of the patient may be adjusted

to the desired mean arterial pressure while the patient is still on CPB; this way, the mean pressure will be in the desired range if the patient generates the desired cardiac output after separation. Then, the heart is filled, a process that is guided by its appearance in the surgical field and on TEE, as well as by the filling pressures (see Fig. 59-3). Wall motion on TEE and cardiac output measurement serve as practical surrogate measures of contractility. Further adjustment of preload may be made by additional filling or draining of the heart by the perfusionist, by adjustment of the operating table position, or by intravenous fluid administration. Adjustment of the afterload to maintain the systemic and pulmonary vascular resistance in the desired range may be made with vasopressors (e.g., phenylephrine, norepinephrine, dopamine) or vasodilators (e.g., nitroglycerin, nitroprusside). In cases of catecholamine-resistant refractory hypotension, vasopressin in dosages of 0.02-0.06 U/min may be attempted.¹⁷³ Inotropic assistance to augment myocardial contractility may be provided by inotropic agents (e.g., epinephrine, dopamine, dobutamine) or phosphodiesterase inhibitors (e.g., milrinone).¹⁷⁴ When pharmacologic and metabolic support prove insufficient, consideration should be given to mechanical support devices (e.g., an intra-aortic balloon pump, ventricular assist devices) or to returning the patient to CPB for further surgical management. Only when the patient is hemodynamically stable after separation from CPB should reversal of heparinization be started.

SPECIAL CONSIDERATIONS

Off-Pump Coronary Artery Bypass

Off-pump coronary artery bypass (OPCAB) involves bypass grafting on a beating heart without using CPB. Although OPCAB was first performed in 1967,¹⁷⁵ the number of OPCABs being performed only peaked in the past decade, when 25% of coronary artery bypass surgeries performed in North America in 2004 were OPCAB.¹⁷⁶

Early retrospective studies suggested OPCAB was associated with a lower incidence of perioperative stroke, decreased postoperative major bleeding, and decreased length of stay and risk-adjusted mortality.^{177,178} However, more recent prospective studies have failed to demonstrate a clear advantage of OPCAB to on-pump bypass,^{179,180} and growing concerns about a higher incidence of incomplete revascularization, decreased long-term graft patency, and increased late mortality in OPCAB have significantly decreased its popularity during the past decade.¹⁸¹⁻¹⁸⁴ Although still controversial, the main role of OPCAB in the future may be in patients with porcelain or severely sclerotic aortas, or patients in whom prolonged heparinization should be avoided.¹⁷⁶

For an anesthesiologist, OPCAB involves more challenging and intensive hemodynamic management, with the potential for instability because of retraction and compression of the heart and consequent potential myocardial ischemia.¹⁸⁵ After sternotomy and exposure of the heart, each target vessel is identified, and a specialized retractor is applied to provide exposure of the target site.

Test occlusion of the target vessel to assess its effect on myocardial function or to provide ischemic preconditioning (or both) is performed in some centers. To perform certain grafts, particularly in the circumflex and posterior descending arteries, the exposure of the target artery will be possible only with the use of stabilization systems.¹⁸⁶ In these cases the heart may be lifted and tilted to improve surgical exposure, and this maneuver may compromise the filling of the cardiac chambers, lowering stroke volume and arterial blood pressure and raising the CVP and right ventricular end-diastolic pressure.¹⁸⁷ The distortion of the mitral and tricuspid annulus may also lead to valve regurgitation,¹⁸⁸ and the compression of the thin-walled right ventricle against the interventricular septum may decrease diastolic filling.¹⁸⁹ A decrease in coronary blood flow of up to 50% has been documented also during exposure of target sites in OPCAB.¹⁹⁰ To maintain coronary perfusion pressure, the patient may be placed in a 20-degree head-down position, given fluids, and supported with a vasopressor (e.g., phenylephrine). Constant communication between the anesthesiologist and the surgeon is the key to preventing unexpected hemodynamic compromise. The diagnosis of ischemia during OPCAB is particularly difficult, because retraction of the heart is associated with a significant decrease in the amplitude of the ECG signal.¹⁸⁵ Furthermore, stabilization devices may produce nonischemic regional wall motion abnormalities on TEE. With lifting of the heart, visualization by TEE is also compromised, and the team must rely on direct visualization of the surgical field and traditional hemodynamic monitors such as an arterial line and a PAC. Proximal anastomoses are performed with a side-biter clamp on the aorta. Systemic blood pressure and aortic wall tension need to be controlled for the application and removal of the side biter.

The level of heparinization required for OPCAB has not been standardized.^{191,192} At some centers, “full” heparinization to maintain the ACT at more than 480 seconds is used, whereas others use limited heparinization to maintain the ACT in the 200- to 300-second range, as is done for vascular procedures. Neither approach has been demonstrated to be clearly superior.

Minimally Invasive Cardiac Surgery

The port-access system is used for minimally invasive cardiac surgery (MICS) that requires the institution of CPB. Preoperative preparation of the patient requires discussion between the surgeon and the anesthesiologist about the exact nature of the surgery planned.^{193,194} The usual intravenous access and monitoring modalities (i.e., those used for conventional cardiac surgery) need to be placed. TEE is an essential modality, and contraindications to the use of TEE would almost preclude port-access MICS. A modified lateral decubitus position is frequently used, and this may have important implications for line placement. To provide lung isolation, a double-lumen tube or a bronchial blocker may be used. Position of the lung-isolating device should be confirmed with a fiberoptic bronchoscope upon placement and again after final positioning of the patient. The bronchoscope should be readily available throughout the

procedure, because any malposition of the tube can result in lung inflation and thus make the surgery almost impossible through the limited incision. Before positioning the patient, external cardioversion pads should be applied for urgent pacing or cardioversion, because the limited access means that internal paddles cannot be employed.

The mainstays of the port-access system are the coronary sinus catheter (CSC) for administration of retrograde cardioplegia, the pulmonary artery vent (PAV), and the endovascular aortic cannula, which also acts as an endovascular clamp (Fig. 59-6). Unlike the regular PAC, the CSCs are not heparin bonded by the manufacturers, so 5000 units of heparin are administered before placement of these types of catheters. Before CSC placement, a persisting left-sided superior vena cava needs to be excluded by TEE. This anatomic variant is asymptomatic and relatively frequent among the general population,¹⁹⁵ occurring in up to 0.3% to 2% of the population.¹⁹⁶ A persistent left-sided superior vena cava drains into the coronary sinus, so it should be suspected if the coronary sinus appears dilated during TEE examination. Injection of contrast into a left-side intravenous line would cause contrast to appear inside the coronary sinus if this abnormality is present.

Under TEE guidance, the success rate of CSC placement has been reported to be 95% and to be superior to fluoroscopy.^{33,197} After successful placement of the CSC, its position is further confirmed by balloon inflation and visualization of the arterialization of the pressure tracing. Although it is not essential, keeping the balloon inflated and the wire loaded into the catheter until immediately before administration of retrograde cardioplegia may help prevent catheter dislodgement. The PAV is also inserted through the right internal jugular vein and guided into the pulmonary artery in the same manner as

FIGURE 59-6 ■ Coronary sinus catheter. Percutaneous cannulation of the coronary sinus for cardioplegia administration in minimally invasive cardiac surgery. The introducer for this catheter was placed in the right internal jugular vein, and the catheter was advanced inside the right atrium and then directed toward the coronary sinus.

a regular PAC. However, central venous pressure cannot be measured with the PAV. Venous access or a drainage line is placed through the femoral vein, and TEE is used to accurately position the cannula. Similarly, the endovascular aortic cannula can be accurately placed under TEE guidance. The positions of the catheters should be confirmed after a change of position from supine to lateral and before commencement of CPB, because poor visibility makes it difficult to reposition the catheters after commencement of CPB.

Regardless of the type of surgery, recognizing intracardiac air and monitoring the success of de-airing maneuvers are always important aspects of TEE examination. The left ventricular apex, which may not be accessible to the surgeon for needle aspiration, needs to be carefully examined by TEE. TEE is the only monitor used to assess the completeness of de-airing.¹⁹⁷

Other factors to consider during MICS include the possible need for urgent cardiac pacing and external cardioversion; suture placement in sites that are difficult to access (which can lead to bleeding); unsatisfactory valve repair resulting in residual regurgitation; and air embolism. Even a small amount of bleeding in a minimally exposed place can result in tamponade after chest closure. The duration of anesthesia and surgery tends to be prolonged, and there is always a risk of a technically unsatisfactory result and need for conversion to an open surgery. At the end of the surgery, the CSC is removed, and, depending on the condition of the patient, the PAV may be replaced with a PAC for postoperative monitoring of the patient.

Robotic-Assisted Cardiac Surgery

Robotic-assisted cardiac surgery (RACS), the next step in the evolution of MICS, is available in only a few places in the world. Its goal is to perform the procedure with as small an incision as possible, with an outcome that would be equivalent or superior to that of the conventional procedure.^{198,199} Anesthetic management for RACS requires all of the techniques outlined earlier for port-access MICS, and the possibility of significantly prolonged surgery and the potential for positional neurovascular injuries (e.g., to the brachial plexus) must also be considered.¹⁹⁹ Preliminary reports indicate faster recovery and a reduction in complications,^{200,201} but long-term results are still pending.

CRITICAL CARE FOR THE ADULT CARDIAC PATIENT

Judson B. Williams • Carmelo A. Milano • Peter K. Smith

CHAPTER OUTLINE

IMMEDIATE POSTOPERATIVE CARE

Initial Evaluation

- Airway and Ventilation
- Neurologic Examination
- Initial Cardiac Auscultation and Electrocardiogram
- Abdominal and Genitourinary Examination
- Peripheral Perfusion
- Body Temperature
- Hemodynamics
- Lines, Tubes, Devices, and Dressings
- Chest Radiograph

Cardiac Surgery with Cardiopulmonary Bypass

Cardiac Surgery without Cardiopulmonary Bypass

Pericardiotomy Syndrome

CARDIAC DYSFUNCTION AFTER CARDIAC SURGERY

Low Cardiac Output Syndrome

- Output and Filling Pressure
- Oxygen Delivery

Preload

Afterload

- Postoperative Effects
- Therapeutic Approaches

Heart Rate

Inotropic Support

Intra-aortic Balloon Pump

Cardiac Tamponade

Vasoplegic Syndrome

Right Heart Dysfunction

Arrhythmias

- Atrial Flutter
- Atrial Fibrillation
- Ventricular Arrhythmias

Graft Occlusion

Echocardiography and Advanced Monitoring

POSTOPERATIVE BLEEDING

Coagulopathy

- Heparin Effect
- Thrombocytopenia
- Thrombasthenia
- Specific Factor Deficiencies

Management of Bleeding

- Crystalloid and Colloid Volume Resuscitation
- Blood Conservation

Pharmacologic Considerations

- Desmopressin
- Aprotinin
- ϵ -Aminocaproic Acid and Tranexamic Acid
- Recombinant Activated Factor VII

NEUROLOGIC COMPLICATIONS

INFECTION

This chapter will familiarize providers with the expected management of patients following adult cardiac surgery using a systematic approach. The common and important side effects or complications of cardiac surgery are described, and their managements are reviewed. The provided references support evidence-based approaches to common postoperative conditions and represent important sources for more detailed analysis of individual topics. The chapter is not meant to be comprehensive but instead focuses on common conditions encountered by those caring for patients in the intensive care unit (ICU) following adult cardiac surgery.

IMMEDIATE POSTOPERATIVE CARE

Initial Evaluation

A systematic evaluation of the patient should be performed immediately on arrival in the ICU. The first step is a structured hand-off or debriefing, which occurs jointly between the surgical, anesthesia, and critical care teams and is critical for patient safety.¹ This structured hand-off may be tailored to individual institutions but should provide a review of the relevant patient history, including comorbid conditions and allergies; pertinent

details of the procedures performed; intraoperative hemodynamic management; discussion of lines, tubes, devices, and dressings; active/ongoing medications; and any expected deviations from routine postoperative care. Although attention may be focused initially on one aspect of the patient's condition (e.g., hypotension), a systematic approach to initial hand-off and evaluation is essential. Following the structured hand-off or briefing, a more detailed evaluation is undertaken by the critical care provider as follows.

Airway and Ventilation

The trachea should be palpated and confirmed to be in the midline, and breath sounds should be auscultated bilaterally. Adequacy of ventilation and absence of tension pneumothorax should be confirmed. The ventilator should be functioning normally and without alarms—if it is not, the patient should be immediately converted to hand-controlled ventilation. The peak inspiratory pressure should be noted. High inspiratory pressures may indicate a tension pneumothorax, inappropriate ventilator settings, or severe pulmonary or chest wall restriction. Pulse oximetry, mixed venous oximetry, and direct measurement of arterial gas tensions are used to confirm adequate oxygen delivery and CO₂ elimination.

Neurologic Examination

Evaluation of the patient's neurologic status should be performed frequently. Uncontrollable hypertension or extreme variability of peripheral vascular resistance may result from severe neurologic injury initially ascribed to residual anesthetic agent.

Initial Cardiac Auscultation and Electrocardiogram

The cardiac examination should document normal heart sounds and the character of any murmurs. The initial electrocardiogram (ECG) may be difficult to interpret because of lead placement changes related to surgical dressings, cardiac pacing, and the presence of conduction abnormalities. Right bundle branch block and first-degree atrioventricular (AV) block occur frequently but usually resolve within the first few postoperative hours. Maintaining a normal sinus rhythm with an adequate rate is important in the early postoperative period when cardiac output may be transiently impaired because of intraoperative ischemia or because of temporary diastolic dysfunction resulting from myocardial edema. First-degree AV block can result in substantial reduction in the instantaneous end-diastolic left ventricular (LV) volume, which determines stroke volume. The use of atrial or AV sequential pacing can overcome these transient derangements, and, in the latter case, it is common to see improved cardiac function with normalization of the AV interval despite abnormal ventricular activation with the ventricular pacing component.

Atrial fibrillation is poorly tolerated in the first postoperative day, and every effort should be made to maintain sinus rhythm, even in patients with preexisting

chronic atrial fibrillation. Immediate cardioversion is often required in the ICU, although atrial fibrillation occurring on the third postoperative day or later is usually well tolerated.

Ventricular arrhythmias may result from early graft failure or coronary spasm, which should be ruled out. A malpositioned pulmonary artery catheter irritating the right ventricular (RV) outflow tract is more easily correctable. Arrhythmias may have many contributing factors (e.g., hypothermia, electrolyte derangement, acid-base imbalances, drug effects), which must be considered and addressed.

Abdominal and Genitourinary Examination

Abdominal examination will reveal the presence of a well-positioned nasogastric or orogastric tube. Exclusion of unexpected masses, organomegaly, pain, or abdominal distention should be documented. Correct placement and securing of the indwelling urinary catheter should be confirmed. Urine should be clear, not concentrated, and free of hemoglobin or frank blood. This is also the time for evaluation of groin or inguinal surgical sites, which are of particular importance when recovering patients following transcatheter and minimally invasive procedures.

Peripheral Perfusion

The adequacy of global and regional perfusion should be assessed by physical examination of the vascular system, including examination of accessible pulse character and the quality of skin and soft tissue perfusion. Intraoperative embolization, vascular injury, or low cardiac output in the setting of peripheral vascular disease may compromise limb perfusion. Special attention should be paid to perfusion distal to any intra-arterial cannulas or lines. This is also the time for evaluation of upper or lower extremity surgical sites as from vessel harvest or vascular cannulation.

Body Temperature

Initial hypothermia is best avoided by expeditious operation and adequate rewarming while the patient is on cardiopulmonary bypass. Hypothermia compromises cardiac function, impairs surgical site healing, causes shivering and increased metabolic demand, interferes with coagulation, and may aggravate or cause rhythm disturbances.² Blankets, other auxiliary warming devices, and fluid warmers for intravenous infusions should be used, particularly in the bleeding patient. Fever is poorly tolerated in the early postoperative period and should be treated aggressively with antipyretics and possibly with intravenous steroids if there is associated hemodynamic compromise.

Hemodynamics

With appropriate cardiac rhythm, the patient should have a cardiac index of greater than 2 liter/min/m² with blood pressure adequate for systemic perfusion. This requires consideration of the patient's age, preoperative blood

pressure, and renal function. The importance of generating adequate cardiac output has been established by several studies with mortality as the outcome variable.³ Acceptance of lower cardiac output occasionally results in good outcome when associated with reasonable mixed venous oxygen saturation (MVO₂) (>55%), adequate urine output (>20 mL/hr without stimulation), and evidence of good peripheral and central perfusion (physical examination, maintenance of acid-base balance). There is no evidence that supranormal cardiac output is beneficial.

Elevated central venous pressure (CVP), especially when associated with facial edema or facial discoloration, must be aggressively evaluated. Possible causes include cardiac tamponade, volume overload, right heart dysfunction, or technical errors that have compromised superior vena caval flow. Elevated pulmonary artery pressures may indicate LV dysfunction or cardiac tamponade, or may be related to preoperative changes in pulmonary vascular resistance. All central pressures should be related to initial values obtained during preoperative studies. Central pressure measurements are also quite sensitive to afterload, which can vary widely and rapidly in the early postoperative course in patients who are often hypovolemic. Elevation of intrathoracic pressure can frequently mimic cardiac failure in the patient with chest wall rigidity because of emergence from anesthetic effect and shivering. The latter process can also increase metabolic demand and reduce MVO₂ to very low levels.

Lines, Tubes, Devices, and Dressings

The type, size, and location at the incisors of the patient's endotracheal tube should be noted. A discussion of the ease of intubation is typically part of the initial debriefing/hand-off with the anesthesia team upon ICU arrival.

All indwelling lines must be confirmed to be functional, particularly those delivering vasoactive drugs. Transport of the patient can partially or completely dislodge intravenous lines. Hemodynamic instability resulting from failure of drug delivery and tissue injury resulting from drug infiltration must be avoided. Mediastinal and pleural space tubes (chest tubes) are placed to underwater seal and are usually set to have -20 cm H₂O suction applied. Mediastinal tubes should be examined for the quantity and quality of drainage. The initial amount of drained blood should be less than 100 mL, and larger amounts should be explained by the surgical team. The initial rate of drainage may reflect drainage of blood or irrigation fluid that has accumulated, particularly in the left thoracic gutter. Nonetheless, an initial assessment of the bleeding rate, tube patency and clotting in the tubes, and correlation of drainage with intravascular volume replacement are critically important. When multiple chest tubes are present, good practice is the labeling of these tubes (e.g., mediastinal vs. pleural, right vs. left) by the operating room nurse to avoid errors and improve communication throughout the patient's recovery.

Pacemaker, intra-aortic balloon pump, or ventricular assist device settings should be recorded. Sutures and dressings securing these various devices at the skin should be confirmed to be intact.

Surgical site dressings are commonly kept intact during the first 48 hours for infection control. If dressings must be disturbed for diagnostic purposes or if they become saturated during this time, strict aseptic technique should be followed. If negative pressure dressings are used or special antimicrobial dressings for lines or devices, then the planned strategy for maintenance of these should be discussed at the initial hand-off upon ICU arrival.

Chest Radiograph

A portable chest radiograph should be obtained and interpreted immediately on arrival. Critical aspects include (1) position of the endotracheal tube, (2) pneumothorax or mediastinal shift, (3) lobar atelectasis, (4) pleural and extrapleural fluid collections, (5) size of the mediastinal silhouette, (6) correct intravascular location of lines, and (7) satisfactory position of radiopaque markers for any devices, sternal wires, or drainage tubes.

Cardiac Surgery with Cardiopulmonary Bypass

Cardiopulmonary bypass (CPB) induces many of the physiologic changes encountered in the postoperative patient, and its duration is a primary determinant of the rapidity of recovery. CPB nonspecifically activates the inflammatory system,⁴ a phenomenon that begins with the interaction of heparinized blood and the bypass circuit.^{5,6} Generalized complement activation is seen, with elevations in C3a and C5a anaphylatoxins after discontinuation of CPB.^{5,7-9} This activation can lead to pulmonary sequestration of leukocytes and the production of superoxides and other products of lipooxygenation.^{5,7} This causes further leukocyte activation and the generation of leukotactic circulating factors that increase the local inflammatory response, including elevations in tumor necrosis factor- α (TNF- α), interleukin (IL)-1, and prostaglandin E₁.¹⁰⁻¹² The generalized inflammatory reaction seen after CPB may change vascular permeability and cause pulmonary hypertension as well as bronchial hyperreactivity.¹³ Together with transient elevations in left atrial pressure, reduced oncotic pressure from hemodilution and increased vascular permeability also contribute to increased pulmonary shunt from the resultant extravascular water.¹⁴

Cellular components that play a significant role in inflammatory response to CPB include circulating cells (platelets, neutrophils, monocytes) and regulatory cells (endothelial cells). Platelets are activated by shear forces, heparin, foreign surfaces, and activated thrombin, a potent platelet agonist. Despite full anticoagulation with heparin, thrombin continues to be generated.¹⁵ The clinical consequences of platelet activation include generation of microemboli, thrombosis, and bleeding from diminution of platelet number and function.¹⁶ Additionally, vasoactive substances may be liberated from platelets in response to CPB or protamine infusion, which can cause pulmonary hypertension and systemic hypotension.¹⁷

Neutrophil activation occurs consequent to the complex interaction of blood with the CPB circuit.

Proinflammatory mediators (e.g., IL-1, -2, -6, and -8, TNF α), complement anaphylatoxins (C3a and C5a), platelet activating factor (PAF), and leukotriene-B4 (LTB4) increase the number of cell surface adhesion molecules and promote neutrophil adhesion to the pulmonary endothelium. Neutrophil adherence and transmigration into the lung occurs under the influence of IL-8. Proteolytic enzyme and oxygen free radical release from activated neutrophils promote further tissue injury and inflammatory activation of endothelial cells.¹⁸

Endothelial cells are a central player in inflammation and coagulation. Specific agonists responsible for endothelial activation have been characterized and include IL-1 β , TNF α , C5a, and thrombin.⁹ Endothelial cell activation results in a procoagulant, vasoconstrictive, and proinflammatory response. Once activated, the anticoagulant properties of the endothelial cell are dramatically reduced, with loss of heparan sulfate proteoglycan, conformational changes in the endothelial cell resulting in increased exposure to tissue factor and von Willebrand factor in the cellular submatrix, increased expression of tissue factor and plasminogen activator inhibitor type 1, and loss of thrombomodulin. The vasoconstrictive effects occur through the production of endothelin-1 and thromboxane A2. Proinflammatory changes are seen with increased expression of P and E selectins and consequent recruitment and sequestration of inflammatory cells.⁶

Cardiac Surgery without Cardiopulmonary Bypass

On-pump coronary artery bypass surgery has been demonstrated by randomized controlled trials to both reduce symptoms and prolong life in every decade since the first coronary artery bypass graft (CABG) procedures were performed in the 1960s. Despite the proven benefits and ever-increasing safety of this procedure, room for improvement remains with regard to neurocognitive complications, atrial fibrillation, transfusions, stroke, and death.¹⁹ Because CPB is perhaps the most invasive aspect of conventional coronary revascularization, and because much of the morbidity of coronary revascularization can be attributed to hypothermic cardiac arrest, aortic cannulation, cross-clamping, and the bypass circuit itself, surgeons may consider performing coronary anastomoses on the beating heart without CPB. Some individual surgeons or institutions perform most coronary revascularization procedures without CPB. The term *off-pump coronary artery bypass (OPCAB)* generally refers to multi-vessel coronary artery bypass performed off the CPB machine, through a standard sternotomy.

Here we will focus on those differences between OPCAB and conventional on-pump revascularization procedures that may substantially impact the patient's recovery. During OPCAB procedures, coronary arteries are individually snared proximally and occluded during the performance of the coronary anastomosis. Depending on whether intracoronary shunts are used, there may be periods of local ischemia without cardioplegic arrest. However, unlike in the conventional on-pump procedures, there are no periods of aortic cross-clamping

and global cardiac arrest. For these reasons, the degree of myocardial stunting during OPCAB may be reduced relative to on-pump procedures. Furthermore, during OPCAB, normothermic pulsatile flow is maintained throughout the procedure, whereas conventional on-pump procedures include a period of nonpulsatile perfusion and generally some degree of systemic cooling and rewarming. Finally, although both techniques require anticoagulation with heparin, many centers practice reduced-heparin dosing for OPCAB. Despite multiple randomized controlled trials, the issue of off-pump versus on-pump myocardial revascularization remains an area of debate.^{20,21} The inflammatory response to CPB appears to be a nonspecific response that includes complement and leukocyte activation.^{4,5,7,10} Although the exact mechanism of activation is unclear, the strongest stimulant for the response is the blood-artificial surface contact that occurs with CPB. This response can be modified by coating the tubing and oxygenator surfaces with biological materials and by improving the hemodynamic performance of the system. Theoretically, by eliminating the heart-lung machine entirely, this response could be significantly reduced.

Several quality studies have investigated the inflammatory response during heart surgery, comparing groups in which coronary revascularization is performed with and without CPB.^{22,23} Angelini and colleagues looked at four important inflammatory markers: neutrophil elastase, an endopeptidase released with neutrophil activation; IL-8, a potent neutrophil chemotactic and activating factor; and C3a and C5a, fragments generated with activation of the common complement pathway.²⁴ These markers were measured at four time-points within the first 24 hours postoperatively. Patients were randomized to two groups: standard coronary revascularization with CPB and OPCAB. The OPCAB group demonstrated significantly lower levels of all four markers and had reduced leukocyte, neutrophil, and monocyte counts. These findings support a reduced inflammatory response with OPCAB; however, the clinical significance of this difference remains unclear. It is interesting that by 4 hours into the recovery period, the activated complement components had decreased in the on-pump group to OPCAB levels.²⁵

OPCAB requires less intraoperative anticoagulation and avoids blood-artificial surface contact, which should reduce platelet activation and destruction. Furthermore, systemic cooling, which may further negatively impact coagulation function, can be avoided with OPCAB. Several studies have compared on-pump procedures to OPCAB and report significant reduction in postoperative bleeding, reduced need for perioperative transfusion, and reduced rate of take-back for bleeding.²⁶ Indeed, when coagulation and fibrinolysis variables have been studied, marked changes in fibrinolytic and coagulation variables occur within the first 24 hours. Conventional on-pump revascularization causes a transient decrease in the platelet count, fibrinogen level, and activation of plasminogen with increased D-dimer formation, which only after 24 hours approximate the levels seen in OPCAB.²⁷ Two contemporary multicenter randomized controlled trials have supported reduced need for blood transfusion and

reoperation for bleeding following off-pump compared to on-pump CABG; however, rates of rate of death, myocardial infarction, stroke, or renal failure requiring dialysis were no different.^{20,21}

Pericardiotomy Syndrome

A specific manifestation of the inflammatory response in cardiothoracic surgery is the post-pericardiotomy syndrome.²⁸ This syndrome, occurring in 10% to 30% of patients, is a self-limited condition beginning in the second or third week after surgery. It is associated with fever and pleuritic, precordial, or substernal chest pain.²⁹ Chest radiographs in patients with post-pericardiotomy syndrome commonly show pleural and pericardial effusions (Fig. 60-1). This syndrome has been associated with specific reactive antibodies and may be seen after any operation that violates the pericardium.²⁹ It is treated with nonsteroidal anti-inflammatory agents, although corticosteroids may be necessary in severe cases.³⁰

FIGURE 60-1 ■ Post-pericardiotomy syndrome is commonly associated with pericardial and pleural effusions. **A**, Chest radiograph on a patient soon after aortic valve replacement shows expected postoperative findings. **B**, Chest radiograph 2 weeks later shows pericardial effusion compatible with the clinical symptoms of post-pericardiotomy syndrome.

CARDIAC DYSFUNCTION AFTER CARDIAC SURGERY

Low Cardiac Output Syndrome

Output and Filling Pressure

Low cardiac output after CPB has historically been recognized as a cause of sudden death.³¹ Low cardiac output resulting from ventricular dysfunction causes a series of adaptive neurohumoral responses as well as geometric changes—dilation and hypertrophy—in the heart. Acute loss of 20% to 25% of functioning myocardium³² causes significant reduction in cardiac output and carries extremely poor short-term³³ and long-term prognoses.³⁴

Measurement and therapeutic manipulation of both cardiac output and central filling pressures are critical to the postoperative care of cardiac surgical patients and are predictive of survival (Fig. 60-2). Central pressures, cardiac output, and venous saturation are routinely measured by means of a flow-directed pulmonary artery catheter. The cardiac index, or cardiac output expressed as liters per minute per meter squared, has a normal range of 2.1 to 4.9 liter/min/m².³⁵ In adults, a cardiac index of at least 2.0 liter/min/m² during the immediate postoperative period is generally required for normal convalescence.

Oxygen Delivery

Shock may be conceptualized as a clinical syndrome resulting from an imbalance between tissue oxygen demand and tissue oxygen supply. The general goals of postoperative care are to prevent shock and provide adequate oxygen delivery. Oxygen delivery of less than 335 mL/min/m² has been associated with a decrease in

FIGURE 60-2 ■ The graph shows the relationship between postoperative cardiac index and probability of death for adults after mitral valve replacement. (Reproduced with permission from Kouchoukos NT: Detection and treatment of impaired cardiac performance following cardiac surgery. In Davila JC, editor: *Henry Ford Hospital International Symposium on Cardiac Surgery*, ed 2, New York, 1977, Appleton-Century-Crofts.)

oxygen consumption and with the development of progressive lactic acidosis.³⁶ Lactic acidosis has been suggested as a metabolic monitor to correlate with total oxygen debt, the magnitude of hypoperfusion, and the severity of shock.^{37,38} However, a direct relationship to total oxygen delivery has been disputed.³⁹ MVO_2 provides a useful index of the adequacy of circulation and reflects, to some extent, mean tissue oxygen level.⁴⁰ MVO_2 is measured with specialized pulmonary artery catheters, and patients with a saturation of less than 60% or those who demonstrate a decrease of more than 5% suffer more frequent postoperative complications.⁴¹ However, others have shown poor correlation between saturation, or trends in saturation, and outcome.⁴² Rapid changes in whole-body oxygen consumption may reduce its overall predictive value.

Adequate regional oxygen delivery is even more difficult to determine. Organ requirements and hormonally activated reflex changes in regional blood supply may occur in the postoperative state. For example, the kidneys, skin, and resting muscles are blood-supply independent and maintain viability by increased oxygen extraction. The heart and brain, on the other hand, are blood-supply dependent, with near maximal oxygen extraction at rest. Sympathetically controlled reflexes compensate for these differences by a shift of blood flow from the skin and splanchnic region at low circulating volumes.⁴³ Splanchnic hypoperfusion is known to be a cause of persistent acidosis.⁴⁴

Acute changes in regional blood supply may be mediated by differing degrees of sympathetic innervation to

precapillary sphincters and arterioles.⁴⁵ Alterations in metabolic activity are common after heart surgery and may be monitored through capnography, which determines the partial pressure of CO_2 in expired gases.⁴⁶ Peripheral vasodilation and shivering during rewarming have been shown to increase metabolic and circulatory demands and can be eliminated with paralysis and sedation, which promotes hemodynamic stability and decreases the need for inotropic support.⁴⁷ A diagnosis of low cardiac output syndrome must include evidence of inadequate oxygen delivery relative to consumption. Objective measurements of cardiac output and MVO_2 must be coupled with clinical evidence of diminished peripheral perfusion and end-organ ischemia to establish the diagnosis of low cardiac output syndrome.

Preload

Maintenance of adequate preload is fundamental in the postoperative management of cardiac surgical patients (Fig. 60-3). The optimal pulmonary capillary wedge pressure in postoperative cardiac surgical patients is unknown, but a range of 14 to 18 mm Hg has been suggested, with increases in extravascular lung water occurring above this level.⁴⁸ Preload correlates directly with the force of ventricular contraction, and the result is a ventricular volume change from end diastole to end systole determined by transmural pressure and compliance of the ventricular wall. Pericardial pressure is normally reflected by the right atrial pressure (Fig. 60-4). However, tight closure of the pericardium may adversely affect transmural

Illustrations for Pulmonary Artery Pressure

FIGURE 60-3 ■ Pulmonary artery pressure waveforms recorded from a pulmonary artery catheter as it passes through the right atrium and right ventricle to the pulmonary artery and wedge positions. Right ventricular end-diastolic pressure is measured at the time of the electrocardiographic (ECG) R wave and is estimated best by the right atrial a wave pressure peak. The a, c, and w waves are recorded from both the right atrium and pulmonary artery wedge positions. (Reproduced with permission from Mark JB: *Atlas of cardiovascular monitoring*, New York, 1998, Churchill Livingstone.)

FIGURE 60-4 ■ Idealized pressure-volume loop for the left ventricle represents a single cardiac cycle. (Reproduced with permission from Chatterjee K, Parmley WW: The role of vasodilator therapy in heart failure. *Prog Cardiovasc Dis* 19:301–325, 1977.)

pressure and decrease stroke volume.^{24,49} Pulmonary artery wedge pressures and the CVP, surrogates for LV and RV volumes respectively, more accurately reflect reduced filling pressures, whereas high filling pressures may be determined by changes in transmural pressure or myocardial compliance rather than accurately reflecting preload.

CVP, the downstream pressure of the systemic venous system, is frequently measured in patients recovering from cardiac surgery. Existing literature focuses on the degree to which CVP gives information on RV end-diastolic pressure and the limitations of CVP as a surrogate variable for left ventricular preload, although the clinical prognostic value of CVP measurement remains unknown.⁵⁰ Many post-cardiac surgery patients are being managed without a pulmonary artery catheter or under “fast-track” protocols for early removal of pulmonary artery catheters.⁵¹ However, CVP usually can be measured in these patients by way of a central venous catheter with its tip in the superior vena cava. Emerging data suggest that CVP may be a useful predictor of patient outcome and the postsurgical patient with elevated CVP may warrant further workup to investigate the cause (renal failure, pericardial tamponade, right heart failure, etc.).⁵²

Most postoperative cardiac surgical patients are relatively hypovolemic and have a labile reactive vasculature.⁵³ In the immediate postoperative period, causes of hypovolemia include large urine volumes, ongoing blood loss, and a significant cross-sectional increase in vascular beds with rewarming. The summation of these physiologic changes is a reduced preload, particularly in the left ventricle. This trend should be anticipated and managed with appropriate volume therapy to prevent precipitous hypotension and low cardiac output. Immediate preload augmentation may be achieved with passive straight leg raising, with a transient 8% to 10% increase in cardiac output,⁵⁴ although this should be viewed as only a temporizing measure and should be quickly supplanted by appropriate volume resuscitation.

Afterload

Postoperative Effects

After a cardiac operation, elevation in afterload is a well-recognized phenomenon. The incidence varies with cardiac pathology, operative procedure, and definition of the resulting hypertension. After valve replacement, the reported incidence ranges between 8% and 12%.⁵⁵ After myocardial revascularization, afterload is elevated in 8% to 61% of patients.^{56,57} Increased systemic vascular resistance at the arteriolar level appears to be the major determinant of arterial pressure after coronary artery surgery.⁵⁸ The cause of postoperative hypertension remains unclear, but contributing factors include decreased baroreceptor sensitivity⁵³ and elevated renin-angiotensin activity.⁵⁹

Sympathetic stimulation and elevated levels of catecholamines also have been identified in the early postoperative period.^{57,60,61} Furthermore, postoperative pain may increase afterload and can be managed with the administration of an analgesic.⁶²

Although pulmonary artery pressures are measured directly (RV afterload), the ascending aortic pressure is inferred by measurements made at a peripheral artery, typically the radial artery. Systolic amplification may occur, elevating the measured systolic radial artery pressure relative to central arterial pressure; however, mean pressures are generally similar between these regions.

In the control of afterload, autoregulation at various sites should be considered. The central nervous system autoregulates mean blood pressures of 50 to 150 mm Hg.⁶³ A reset lower limit for autoregulation may be higher in hypertensive patients.⁶⁴ Renal autoregulation requires a mean blood pressure of 70 mm Hg.⁴³ The heart with residual coronary disease also requires adequate mean arterial pressure (65 mm Hg), as do patients with pathologic concentric myocardial hypertrophy.⁶⁵

Acute afterload reduction in the postoperative period is frequently beneficial (Fig. 60-5). However, afterload reduction with low filling pressures often produces a compensatory tachycardia, which may be deleterious. In addition, adequate preload must be achieved before the institution of vasodilating agents. When applying afterload reduction to patients with high filling pressures, there is usually no change or a slight reduction in heart rate. Experimental evidence suggests that afterload reduction, when applied to low or normally filled ventricles, may increase infarct size⁶⁶; when applied in a setting of high preload, infarct size may be reduced.^{67,68} This may have implications in patients after incomplete myocardial revascularization.

Therapeutic Approaches

Afterload reduction generally improves cardiovascular function and diminishes preload. The degree to which hemodynamic improvement can be obtained with afterload reduction is difficult to predict. Therapeutic results depend on the end-systolic pressure–volume relationship of each patient. Preload augmentation coupled with afterload reduction has additional positive effects on

FIGURE 60-5 ■ Acute postoperative afterload reduction. Two idealized pressure-volume loops are at the same level of contractility and end-diastolic volume (EDV), but with a reduction in arterial pressure from loop B to loop A, which results in an increase in stroke volume. EDP, End-diastolic pressure. (Reproduced with permission from Chatterjee K, Parmley WW: The role of vasodilator therapy in heart failure. *Prog Cardiovasc Dis* 19:301–325, 1977.)

overall cardiac function.⁶⁹ Afterload reduction also improves forward ejection in patients with residual mitral and aortic insufficiency.^{70,71}

Although various afterload-reducing agents are available, nitroglycerin, nitroprusside, and nicardipine are among the frequently used agents in the immediate postoperative period. Nitroglycerin improves coronary collateral flow and may prevent coronary spasm, and it is frequently used for the first 12 to 24 hours after coronary revascularization.^{72,73} Nicardipine is short-acting, does not have direct myocardial contractility effects, and is growing in popularity with regard to aortic surgery. Nitroprusside is similarly short-acting but may increase ST-segment elevation in perioperative ischemia and cause significant intracoronary shunt.⁷² Nonetheless, nitroprusside continues to be used for the acute management of postoperative hypertension, mandating a knowledge of this agent's adverse effects.⁷⁴

When nitroprusside is used at high doses (greater than 7 µg/kg/min) for prolonged therapy, cyanogen, cyanide, and thiocyanate are potential toxic breakdown products. Signs of toxicity are subtle and include a narrowing of the arteriovenous oxygen difference and the development of metabolic acidosis.⁷⁵ Thiocyanate levels may be measured under these circumstances, with levels of 50 to 100 mg/liter associated with cyanate toxicity, and 200 mg/liter may be lethal. Discontinuance and dialysis are the mainstays of treatment, although prophylactic infusion of hydroxocobalamin (25 mg/hr) has been shown to decrease cyanate concentration. In surgery for aortic disease, nitroprusside has been shown to be associated with an increased incidence of neurologic complications believed to be referable to reduced spinal cord blood flow.⁷⁶

Alternative parenteral agents should be considered when high-dose nitroprusside therapy is necessary. Intravenous nitroglycerin may achieve afterload reduction as

well as coronary dilation. Hydralazine, although longer acting, may also be effective.⁷⁷ Nicardipine is a calcium channel blocking agent with effects more selective to vascular smooth muscle as opposed to cardiac muscle and does not impede myocardial function. Beta blockers are effective in the management of postoperative hypertension and are being used more commonly in patients with LV failure. Esmolol, a short-acting selective beta blocker, may be particularly useful in this setting, although these agents may have a significant negative inotropic effect.

Many patients require afterload reduction throughout their postoperative course. Patients with persistent hypertension and with reduced LV function will benefit from long-term afterload reduction and should be converted to oral medications. Chronic afterload reduction, in patients with significant congestive heart failure, has been shown to have a positive impact on survival. In patients with symptomatic congestive heart failure (New York Heart Association [NYHA] class II and class III), a significant reduction in long-term morbidity and mortality has been seen in those treated with enalapril, an angiotensin-converting enzyme (ACE) inhibitor.⁷⁸ Additional studies have confirmed that ACE inhibitors are particularly useful for afterload reduction in patients with heart failure.^{79,80} Patients with asymptomatic LV dysfunction (NYHA class I and class II) may also benefit from long-term therapy with ACE inhibitors or aldosterone antagonist therapy. Echocardiographic studies in post-myocardial infarction patients have shown that ACE inhibitors attenuate LV enlargement.⁸¹ Nitrates and hydralazine have also been used but are less effective than ACE inhibitors.⁸² Recently, in a large community-based study, decreased hospital readmission for symptoms of congestive heart failure has been associated with the prescription of aldosterone antagonist therapy among older patients hospitalized with heart failure and reduced ejection fraction.⁸³

Heart Rate

The postoperative control of heart rate is important and encourages standard application of temporary, epicardial, bipolar atrial, and ventricular pacing wires in most patients. Normal sinus rhythm, through synchronized end-diastolic preload augmentation, is responsible for approximately 25% of cardiac output in the postoperative setting (Fig. 60-6).⁸⁴ Changes in heart rate are common after cardiac surgery and include sinus bradycardia, junctional rhythm, and first-, second-, or third-degree heart block. These phenomena are usually transient and may be related to perioperative beta blockade, intraoperative antiarrhythmics, or metabolic damage during cardioplegic arrest including potassium or magnesium abnormalities.⁸⁵ Inadequate myocardial protection may cause ischemia of the conduction system.⁸⁶ Permanent injury to the conduction system is most often the result of direct surgical injury during intracardiac procedures. Management of disturbances in heart rate must be individualized. Simple atrial pacing (in the range of 90 to 110 beats/min) is optimal for sinus bradycardia. With AV nodal blocks, AV pacing with an interval in the range of 150 to 175 msec is usually optimal.^{87,88} The AV interval also depends

FIGURE 60-6 ■ Synchronized end-diastolic preload augmentation. A comparison of cardiac output with ventricular pacing (without synchronous atrial systole) and with atrial pacing shows an overall increase in cardiac output with atrial pacing of approximately 26% in patients after cardiac surgery. (Reproduced with permission from Hartzler GO, Maloney JD, Curtis JJ, et al: Hemodynamic effects of atrioventricular sequential pacing after cardiac surgery. *Am J Cardiol* 40:232–236, 1977.)

FIGURE 60-7 ■ Cardiac output with atrioventricular (AV) sequential versus atrial pacing. A comparison of AV sequential pacing and atrial pacing in patients with a prolonged postoperative PR interval (intrinsic and paced PR intervals are shown in milliseconds to the left for atrial pacing and to the right for AV sequential pacing). Note the uniform increase in cardiac output that is induced by pacing, despite absolute differences in the shortening of the PR interval, and the overlap between paced PR intervals and intrinsic PR intervals between patients. (Reproduced with permission from Hartzler GO, Maloney JD, Curtis JJ, et al: Hemodynamic effects of atrioventricular sequential pacing after cardiac surgery. *Am J Cardiol* 40:232–236, 1977.)

on selected heart rate (Fig. 60-7). The normalization of AV synchrony by these means is associated with a loss of the normal ventricular activation sequence, depressing ventricular function at constant preload and afterload by approximately 10% to 15%. Optimal heart rate determination must be individualized for each patient with reference to measurements of cardiac output.

When in place, temporary pacing wires constitute a direct current pathway to the heart and must be insulated when not in use. Caution is needed when connecting a rapid-pacing device to the wires to ensure atrial connection. Temporary pacing wires are usually removed in the early postoperative period but may be left in place indefinitely. High pacing thresholds usually develop within 2 weeks, unlike permanent endocardial electrodes. When temporary pacing is not possible, bradyarrhythmias may be treated pharmacologically with atropine or isoproterenol. Alternatively, a pulmonary artery catheter with an additional pacing port or a transthoracic pacemaker may be used.⁸⁹

Inotropic Support

Inotropic agents may be necessary to achieve adequate cardiac function (Fig. 60-8) and to maintain peripheral oxygen delivery. Improvement in cardiac function by pharmacologic intervention is generally achieved at the expense of increased myocardial oxygen consumption. Wide variability among cardiac surgery centers exists with regard to the routine use of inotropic and vasoactive medications, with some centers using positive vasoactive medications for almost all patients.⁹⁰ In general, inotropic agents should be considered only after manipulations of heart rate, preload, and afterload have been maximized. Myocardial function typically improves throughout the postoperative course, allowing weaning from inotropic support.⁹¹

FIGURE 60-8 ■ Pressure-volume loops inscribed under conditions of constant preload and afterload. An induced increase in inotropic state from loop A to loop B shifts the end-systolic pressure-volume relationship (dashed lines) and results in increased stroke volume in loop B. (Reproduced with permission from Chatterjee K, Parmley WW: The role of vasodilator therapy in heart failure. *Prog Cardiovasc Dis* 19:301–325, 1977.)

Various inotropic agents are available, and all are administered by either intravenous bolus or continuous infusion. These agents should be administered through a central venous or pulmonary artery catheter whose intravascular position has been ascertained to prevent perivascular infiltration. Most inotropic agents act through stimulation of adrenergic receptors (Table 60-1). β -Adrenergic agonists mediate an increase in intracellular calcium concentration.⁹² Clinical experience with multiple inotropic agents has demonstrated synergism despite in vitro evidence that the maximal positive inotropic effect of one drug precludes augmentation by another.⁹³ This may be because of alterations in the adenylate cyclase system in patients with heart failure, or because of alterations in beta-adrenoreceptor density.^{92,94-96}

Nonadrenergic inotropes include digoxin, calcium chloride, phosphodiesterase inhibitors (amrinone, milrinone, and enoximone), and triiodothyronine. The presence of metabolic acidosis may interfere with the effectiveness of inotropic agents.⁹⁷ Most inotropic agents, most importantly β -adrenergic agonists, have proarrhythmic effects. Improved cardiac output must be balanced against risks of inducing either atrial or ventricular arrhythmias. Patients who require high doses of dopamine, epinephrine, or norepinephrine experience dangerous vasoconstrictive effects because of the α -adrenergic agonist effect of these agents at higher doses. This effect can result in limb, mesenteric, or renal ischemic injury.

Intra-aortic Balloon Pump

Mechanical ventricular support should be considered before the patient suffers significant end-organ hypoperfusion, which may impede ultimate recovery. Insertion of an intra-aortic balloon pump (IABP) via a percutaneous femoral arterial approach is the initial step in mechanical ventricular support. A properly functioning IABP provides increased diastolic coronary perfusion and augmented cardiac output by reducing LV afterload (Fig. 60-9). Greater deterioration of ventricular function may warrant assist devices that provide complete support; these devices are used as bridges to either myocardial recovery or possible cardiac transplantation.

Cardiac Tamponade

Cardiac tamponade results from occupation of the mediastinal space by fluid or clotted blood, which restricts the end-diastolic volume of both ventricles. It has been reported to occur acutely in 3% to 5% of open heart surgery cases.⁹⁸⁻¹⁰⁰ The constellation of findings associated with acute postoperative cardiac tamponade includes (1) increased variation in blood pressure with respiration (pulsus paradoxus); (2) equalization and elevation of the CVP, pulmonary artery diastolic pressure, and left atrial pressure or pulmonary artery wedge pressure¹⁰¹; (3) a fall in urine output (often an early finding); (4) excessive chest tube drainage or, paradoxically, minimal or no chest tube drainage, especially with heavy clots noted within the chest tubes; (5) mediastinal widening on chest film; (6) low cardiac output (late); and (7) hypotension (late). No single finding or combination of findings is sufficient to establish the diagnosis, and a high index of clinical suspicion should be maintained. Early postoperative tamponade is treated by reoperation. Patients in extremis may require reopening of their sternotomy in the ICU. Temporizing management consists of (1) volume loading, (2) reduction of airway pressure (removal of positive end-expiratory pressure [PEEP], anesthetizing agents, diminishing tidal volume with increasing ventilatory rate), and (3) inotropic support.

Cardiac tamponade may be present with any amount of retained blood or fluid, which commonly is circumferential but which may be loculated and still adversely affect cardiac function.^{102,103} In patients with decreased ventricular function, smaller amounts of space occupation will result in tamponade physiology.¹⁰⁴ For patients with severe ventricular dysfunction, simple reapproximation of the sternum after cardiac surgery may not be possible. Delayed sternal closure may be necessary in 1% to 2% of high-risk patients, and subsequent closure is usually possible between 1 and 4 days after initial operation.¹⁰⁵

To a certain extent, the pleural and mediastinal spaces are continuous, and resulting intrathoracic pressure is distributed to affect the lungs and cardiac chambers simultaneously. An open pericardium and pleural space

can neither prevent nor minimize cardiac tamponade. Increases in airway pressure, which may result from changing lung compliance or the application of PEEP, or a change in chest wall compliance may be directly transmitted to the heart. Such increases in airway pressure cause additive space occupation and may result in tamponade physiology at lower volumes of retained fluid.

Although cardiac tamponade usually presents within the first 24 hours after surgery, there is a definite incidence of late presentation.^{103,106} Most cases occur in patients with large amounts of postoperative bleeding, those who require anticoagulation, or those with active inflammation (post-pericardiotomy syndrome). Delayed diagnosis is attributed to the associated nonspecific symptoms of malaise, dyspnea, chest pain, and anorexia. Echocardiography remains the mainstay in diagnosis of delayed cardiac tamponade.¹⁰⁷⁻¹⁰⁹

Vasoplegic Syndrome

CPB induces a systemic inflammatory response that in some patients may manifest as vasodilatory shock. The clinical state of profound hypotension, low systemic vascular resistance, massive volume requirement, and increased use of vasopressors is called vasoplegic syndrome (VS). This syndrome has generally been defined as an arterial pressure of less than 50 mm Hg, a cardiac index of greater than 2.5 liter/min/m², a right atrial pressure of less than 5 mm Hg, a left atrial pressure of less than 10 mm Hg, and low systemic vascular resistance (<800 dyne • sec/cm⁵).¹¹⁰ The incidence of VS has been reported to range between 8% and 10% after cardiac surgery and up to 42% after left ventricular assist device (LVAD) placement.^{111,112}

Several factors are associated with VS, including preoperative intravenous heparin, ACE inhibitors, and

calcium channel blockers, with reported incidences as high as 56%, 44%, and 47%, respectively. Other reported risk factors include the use of alcuronium, the presence of diabetes, the use of protamine, and preoperative heart failure.¹¹² The mortality associated with this condition is considerable.¹¹³ Standard vasopressors such as norepinephrine, phenylephrine, or vasopressin have been used both intraoperatively and postoperatively to provide hemodynamic support. However, a small percentage of patients remain in vasodilatory shock despite aggressive treatment. In these patients, methylene blue has been demonstrated to be well tolerated, to significantly increase systemic vascular resistance, and to reduce mortality when given as an intravenous infusion (1.5 to 2 mg/kg over 20 to 60 min).¹¹² Side effects of methylene blue include arrhythmias; vasoconstriction of coronary, renal, mesenteric, and pulmonary vascular beds; reduced cardiac output; and angina. Most side effects, however, are dose dependent and do not occur with dosages of less than 2 mg/kg.¹¹⁰ It should not be used in patients with severe renal insufficiency, with hypersensitivity to previous administration, or with glucose-6-phosphate dehydrogenase (G6PD) deficiency. Also, it should be used with caution in patients receiving dapsone because of its potential to cause hemolytic anemia. Although use as a rescue agent is occasionally warranted, the data are not sufficient to support use as a first-line agent.¹¹²

Right Heart Dysfunction

Although right heart dysfunction is most commonly secondary to left heart failure, it may occur as an isolated condition. In this setting, the left ventricle (LV) may display relatively preserved intrinsic function, but cardiac output remains low because of poor LV filling. Other important manifestations of isolated right heart failure

include elevated CVP, poor RV contractility, and elevated pulmonary vascular resistance. With severely impaired RV function, pulmonary artery pressures may not be elevated. Treatment strategies for isolated right heart dysfunction are similar to those used to manage a low cardiac output state caused by more conventional LV dysfunction. RV preload, as measured by the CVP, may need to be increased to greater than 20 mm Hg. Heart rate and rhythm should be optimized (sinus rhythm, rate 90 to 100). β -Adrenergic receptor agonists may be helpful, but higher doses of epinephrine, norepinephrine, or dopamine may further increase pulmonary vascular resistance and exacerbate right heart failure. Milrinone is an important agent in these circumstances, because it provides a positive inotropic effect for the right ventricle but also reduces pulmonary artery pressures as well as pulmonary vascular resistance. Finally, inhaled nitric oxide represents the most specific pulmonary vasodilator; nitric oxide, unlike milrinone, does not induce systemic hypotension. The starting dose for inhaled nitric oxide is typically 20 parts per million. A final strategy for isolated right heart failure is a RV assist device. In general, this invasive strategy should be used only after less invasive approaches have failed.

Arrhythmias

Atrial Flutter

Atrial flutter is generated by a macro-reentrant phenomenon and can be treated rapidly and effectively with electrical stimulation.¹¹⁴ Although this arrhythmia may be interrupted by a single, appropriately timed atrial extrasystole, it is most commonly interrupted by one of the following methods: (1) Entrainment, which is accomplished by determining the atrial rate and instituting atrial pacing at a slightly higher rate to capture the atria. Regularization of the ventricular response and an altered P-wave morphology are usually produced. Termination of pacing is then ordinarily followed by normal sinus rhythm (Fig. 60-10). (2) Nonspecific rapid atrial pacing or stimulation.¹¹⁵ Rapid atrial pacing is performed by introducing trains of atrial pacing at rates in the range of 450 to 600 beats/min. Short trains (less than 1 second) effectively introduce single extra stimuli within the effective refractory period of the pacing site and thus can interrupt atrial flutter and reinstate the normal sinus rhythm. If the train of rapid atrial pacing is too long, it may induce atrial fibrillation, which cannot be treated with these pacing techniques. However, in the atrial fibrillation that may ensue, the ventricular response is usually slower and thus better tolerated than that of atrial flutter.¹¹⁶ Moreover, it is not uncommon for atrial fibrillation induced in this manner to revert spontaneously to normal sinus rhythm.

Atrial Fibrillation

Incidence and Risk. Atrial fibrillation is the most common supraventricular arrhythmia after cardiac surgery. The incidence has varied from 28% to 54% of patients undergoing cardiac operations.^{99,100,117,118} The

FIGURE 60-10 ■ Atrial flutter in postoperative cardiac patients. Electrocardiograph leads II and III show atrial flutter with 2:1 atrioventricular block. A and B are not continuous. At the *black dot* in A, the P-wave morphology has changed from negative to positive, which indicates entrainment. In B, after 30 seconds of pacing at 350 beats/min, atrial pacing is terminated (*open circle*). Sinus rhythm appears spontaneously. S, Stimulus artifact. (Reproduced with permission from Waldo AL, MacLean WAH: *Diagnosis and treatment of cardiac arrhythmias following open-heart surgery*, Mt. Kisco, NY, 1980, Futura.)

cause is unknown, but atrial fibrillation may result from (1) unprotected ischemia,¹¹⁹ (2) multidose cardioplegic solution administration with high potassium concentration,⁸⁵ (3) atrial dilation or inadequate atrial protection,¹²⁰ or (4) postoperative pericarditis.¹²¹

The incidence of postoperative atrial fibrillation is higher in patients with echocardiographic evidence of pericardial effusion. Certain patients may also have an inherent propensity to develop supraventricular arrhythmias related to the preoperative accumulation of catecholamines in intramyocardial axons.¹²² Additional risk factors predictive of an increased incidence of atrial fibrillation include advanced age, chronic obstructive pulmonary disease, prolonged cross-clamp periods,¹²³ and discontinuation of preoperative beta blockers. Although this arrhythmia has not been shown to increase the 30-day mortality rate, it does prolong length of hospital stay in patients undergoing CABG. Furthermore, there is an increased incidence of malignant ventricular rhythms (both ventricular tachycardia and ventricular fibrillation) and a significant increase in the postoperative stroke rate.¹²³

Diagnosis and Treatment. Diagnosis is by direct examination of atrial and ventricular bipolar ECGs.¹¹⁵ The presence of chaotic and rapid atrial depolarization indicates atrial fibrillation, whereas a regular rapid atrial depolarization with an organized ventricular response (usually 2:1 or 3:1) indicates atrial flutter (Fig. 60-11). Therapeutic objectives in patients with atrial fibrillation, in order of importance, are (1) heart rate control, (2) conversion to sinus rhythm, and (3) prevention of embolic complications. Rapid supraventricular arrhythmias causing significant hemodynamic compromise should be treated by cardioversion or defibrillation. In hemodynamically stable patients, one therapeutic option

FIGURE 60-11 ■ Bipolar atrial electrogram (AEG) showing atrial flutter is seen in the upper trace, with simultaneous electrocardiograph leads II and III that show atrial flutter with 2:1 atrioventricular block. Recording speed is 25 mm/sec. (Reproduced with permission from Waldo AL, Cooper TB, MacLean WAH: *Cardiac pacing in the treatment of cardiac arrhythmias following open heart surgery: use of temporarily placed atrial and ventricular wire electrodes*. In Samet P, El-Sherif N, editors: *Cardiac pacing*, ed 2, New York, 1980, Grune & Stratton.)

for controlling ventricular response is a calcium channel antagonist: either verapamil, administered in 2.5- to 5-mg boluses to a total of 20 mg, or diltiazem given as an intravenous load followed by a continuous infusion. Diltiazem is given as a 0.25 mg/kg bolus over 2 minutes followed by an infusion of 10-15 mg/hr. These agents rapidly reduce the ventricular response by increasing AV block.¹²⁴ Verapamil is more negatively inotropic than diltiazem and must be used with caution in patients with heart failure and low cardiac output syndrome; however, the salutary effect of reduction in ventricular rate is usually more important than the negative inotropic effect of these drugs.¹²⁵ Adverse effects of calcium channel antagonists may be treated with calcium infusion, glucagon, or inotropic agents.¹²⁶⁻¹²⁸

Alternatively, beta blockers, especially those with short action (esmolol), have been studied for the acute management of atrial fibrillation. The response to beta blockade varies considerably when it is used to treat atrial fibrillation in the post-CABG patient. In addition, hypotension may be a significant side effect in as many as 20% to 40% of patients treated. Digoxin has been similarly used, although immediate heart rate control is rarely achieved.¹²⁹ Multidrug combinations can be hazardous in patients without temporary pacing wires. The combination of digoxin, verapamil, and a β -adrenergic antagonist can lead to complete heart block, and verapamil and a β -adrenergic antagonist may lead to sinus arrest.¹³⁰ Once heart rate control has been achieved, conversion to and maintenance of sinus rhythm with an antiarrhythmic agent may be necessary.

Two agents that have been used extensively for postoperative atrial fibrillation are amiodarone and sotalol. Relative to class IA agents, these drugs are believed to have equivalent efficacy and improved side effect profiles. These agents are very effective at converting atrial fibrillation, and both retard AV nodal conduction, thereby

reducing the ventricular response to atrial fibrillation. Amiodarone is typically administered as a 1-g intravenous infusion, which is given over a 24-hour period, with the initial 150 mg given over 20 minutes. Subsequent doses are given orally (400 mg, three times a day). Sotalol is available only as an oral preparation, 40 to 160 mg, given twice a day. A common approach is to first attempt chemical cardioversion with these agents, and if this fails, to perform electrical cardioversion. Sotalol can induce significant bradycardia and generally should not be combined with other beta blockers. In addition, harmful proarrhythmic effects, including ventricular tachycardia, have been described with sotalol. The incidence of these harmful rhythms has correlated with QT prolongation, and this should be monitored. Chronic amiodarone therapy can induce pulmonary fibrosis and hypothyroidism. In general, the risk of postoperative atrial fibrillation is considerably reduced after the first month, and antiarrhythmics initiated for isolated postoperative atrial fibrillation should be discontinued after this point.

There has been much interest in the prophylactic use of antiarrhythmic agents to diminish the incidence of supraventricular arrhythmias (atrial fibrillation, in particular) after cardiac surgery. However, prophylactic use of antiarrhythmics in all patients may lead to unwanted side effects in patients who would otherwise convalesce normally. As attempts to identify perioperative risk factors continue, many prefer to treat arrhythmias only when they are present.¹³¹

Ventricular Arrhythmias

Sustained ventricular arrhythmias are an uncommon postoperative issue but are life threatening and require a prompt and organized treatment strategy. Immediate electrical cardioversion should be followed by a thorough investigation for treatable causes, which may include electrolyte imbalance, hypoxia, malpositioned Swan-Ganz catheter, and proarrhythmic effects of inotropes or other agents. Myocardial ischemia should always be ruled out as the cause of the ventricular arrhythmias. A 12-lead ECG should be performed, and if ischemic changes are present, catheter-based coronary angiography should be promptly considered. Persistent ventricular arrhythmias in the postoperative patient lead quickly to hypoperfusion and a dangerous spiral. For this reason, early placement of IABP for ventricular assistance is often helpful. Persistent arrhythmias also warrant initiation of either lidocaine or amiodarone intravenously. Formal electrophysiologic testing and an implantable defibrillator may be indicated. Ventricular arrhythmias occur frequently after left ventricular assist device implantation in end-stage heart failure, often with implantable cardioverter-defibrillator required.¹³² Among patients undergoing transcatheter aortic valve replacement, heart block requiring permanent pacemaker implantation is emerging as one of the predominant complications of these procedures.¹³³

Graft Occlusion

Early graft failure usually results from technical factors, although it may be produced by scarring and is seen more

frequently in patients with inflammatory pericardial syndromes. Early graft failure may manifest as ventricular arrhythmias or as hemodynamic compromise with evidence of ischemia; alternatively, the occurrence may be clinically silent. Factors that affect the presentation include the nature of the collateral blood supply from other grafts or from the native coronary circulation. Also important is the amount of viable myocardium at risk. Patients with ventricular arrhythmias, hemodynamic change, and evidence of ischemia warrant urgent coronary angiography. Graft failure can be addressed with percutaneous interventions, or the patient can be returned to the operating room for graft revision. Perioperative myocardial infarction is defined by ECG changes, serum biomarker measurements, and the development of new regional LV dysfunction. Perioperative myocardial infarction does not result solely from graft or coronary occlusion; it may also result from compromised myocardial protection or atheroembolic events. Treatment is mainly supportive, with intravenous nitroglycerin and afterload reduction. Inotropic agents or IABP may be required during a period of myocardial recovery.

Graft patency is enhanced by the perioperative administration of antiplatelet agents. Early graft occlusion after CABG is known to result from platelet thrombus due to endothelial damage and altered blood flow in the graft. Clopidogrel is thought to potentially act in a synergistic fashion with aspirin in preventing the early platelet thrombus in bypass grafts. Initially, aspirin and dipyridamole have been used, but subsequent work suggests that low-dose aspirin alone is as effective as a combination of agents.^{134,135} Aspirin should typically be administered the morning after surgery. Clopidogrel bisulfate has also been considered for postoperative antiplatelet therapy. Clopidogrel is an inhibitor of adenosine diphosphate (ADP)-induced platelet aggregation. It acts as a direct inhibitor of ADP by binding ADP receptors on platelets and preventing the subsequent ADP-mediated activation of the glycoprotein IIb/IIIa complex. The clinical evidence for the efficacy of clopidogrel in patients with coronary artery disease is derived from the Clopidogrel versus Aspirin in Patients at Risk of Ischemic Events (CAPRIE) trial.¹³⁶ Among surgical patients, Clopidogrel After Surgery for Coronary Artery Disease (CASCADE), a small randomized placebo-controlled trial, evaluated the impact of clopidogrel and aspirin versus aspirin alone on graft patency and clinical outcomes after CABG throughout 1 year. Patients first received the study drug, without bolus, when postoperative chest tube drainage had decreased to less than 50 mL/hr for 2 consecutive hours. Investigators found a nonsignificant 14.8% reduction in the primary outcome of intravascular ultrasound-measured vein graft intimal hyperplasia in the clopidogrel group. Additionally, in this small trial that was underpowered for clinical events, there were no differences in secondary endpoints of vein graft patency, postoperative cardiovascular events, or major bleeding.¹³⁷

Postoperative clopidogrel is currently recommended in addition to aspirin for patients who undergo CABG following non-ST-segment elevation acute coronary syndromes and for aspirin-allergic patients. It remains to be evaluated whether newer, more potent antiplatelet agents, including the thienopyridine prasugrel and reversible

ADP antagonist ticagrelor, as well as novel anticoagulants, including factor X and II inhibitors, might improve post-CABG angiographic and clinical outcomes.¹³⁸

Echocardiography and Advanced Monitoring

Multiplane transesophageal echocardiography (TEE) has become commonplace for intraoperative monitoring during cardiac surgery. TEE is used to measure myocardial and valvular function, identify aortic dissection, assess de-airing of the heart, confirm placement of cannulae, and more. In the postoperative patient, TEE is also used for single-episode assessment of function, to assess for thrombus or pericardial tamponade, and to guide therapies such as cardioversion or IABP placement. However, the ideal method of advanced cardiovascular monitoring for guiding hemodynamic treatment in the postoperative patient is one that is reliable, continuous, noninvasive, operator-independent, and cost-effective.

Transthoracic echocardiography (TTE) is commonly used and often quite valuable in the management of post-cardiac surgery patients. Although less invasive than TEE, TTE use is also limited in the immediate postoperative period by the presence of an open chest, dressings, tubes, and lines; by difficulty in allocating technicians, machines, and probes; and by the single snapshot of data provided. More continuous hemodynamic monitoring is generally not possible with TTE.

Recently, a flexible, miniaturized, and disposable TEE probe has been approved by the U.S. Food and Drug Administration (FDA) and may remain in situ for 72 hours. These probes provide the benefit of performing frequent direct qualitative and quantitative assessments of myocardial function in the dynamic post-cardiac surgery patient. Conventional TEE probes are 10 to 15 mm in diameter, whereas the miniaturized probe is 5.5 mm in diameter and may be placed by intensivists. Recent studies have indicated that the miniaturized indwelling TEE probes are useful for better defining clinical scenarios in unstable patients and in patients being weaned from venoarterial extracorporeal membrane oxygenation.¹³⁹

A number of technologies have been developed to provide clinicians with continuous indexes of cardiovascular function to guide decision making and responses to therapy. Minor invasive arterial thermodilution remains the standard for the estimation of cardiac output. Less invasive and continuous techniques such as pulse contour cardiac output and arterial waveform analysis are also available although concerns persist regarding the accuracy and reliability of these techniques. Noninvasive continuous techniques such as bio-impedance and bio-reactance require further investigation.

Esophageal Doppler monitoring (EDM) measures blood flow velocity in the descending thoracic aorta using a flexible transesophageal Doppler ultrasound probe similar in size to a nasogastric tube. Cardiac output and stroke volume are estimated using an estimate of aortic cross-sectional area derived from the patient's age, height, and weight. EDM allows optimization of a patient's volume status or LV preload, and experience with use of

this probe is growing among anesthesia and critical care providers. The EDM probe is significantly smaller than a traditional TEE probe and provides continuous data as opposed to a single snapshot.¹⁴⁰

POSTOPERATIVE BLEEDING

Postoperative bleeding is always present to some degree after cardiac surgery. Bleeding is related to a combination of mechanical factors as well as coagulopathy. A surgically correctable cause predominates in less than 3% of cases and is indicated by brisk hemorrhage (>200 mL/hr), normal or near-normal coagulation studies, and the appearance of blood clots in the mediastinal drainage tubes. The amount of bleeding that occurs after surgery, the number of transfusions required, and the filtering of transfused components are related to outcome.¹⁴¹

Coagulopathy

Coagulopathy is a common feature of patients recovering from cardiac surgery. There exist multiple opportunities for intervention in the pathway to adequate sustained clot formation (Fig. 60-12). Following CPB, the predominant cause of abnormal bleeding is a fall in platelet number and impaired platelet function. Its effects are exacerbated by the preoperative use of antiplatelet agents,

thrombolytic agents, and heparin.^{142,143} Hypothermia associated with CPB also contributes to decreased platelet function and postoperative coagulopathy and hemorrhage.^{98,144,145} Platelet dysfunction is related to passage through the extracorporeal circuit, with resulting decrease in platelet membrane receptors for fibrinogen as well as for glycoprotein Ib and glycoprotein IIb/IIIa complex. A second important mechanism for coagulopathy is progressive fibrinolytic state of variable intensity related to the length of time of the CPB. Fibrinogen is critical for effective clot formation, and its monitoring and guided supplementation in the treatment of major bleeding is increasingly recognized.¹⁴⁶

Coagulopathy may be associated with variable or no bleeding and is recognized by the presence of abnormal clotting parameters (prothrombin time [PT], partial thromboplastin time [PTT], fibrinogen level, platelet count) and the absence of solid clot formation in the mediastinal drainage tubes. Algorithms involving point of care testing, including thromboelastography and thromboelastometry, have the potential to reduce transfusion requirements.¹⁴² Any or all of the following abnormalities may be present and should be considered.

Heparin Effect

The heparin effect is demonstrated by a prolonged PTT or a prolonged activated clotting time (ACT), or both.

FIGURE 60-12 ■ An overview of clot formation, demonstrating points of intervention. AVP, Arginine vasopressin; DDAVP, desmopressin; PCCs, prothrombin complex concentrates; rFVIIa, recombinant factor VII; TF, tissue factor; vWF, von Willebrand factor. (Reproduced with permission from Sniecinski RM, Levy JH: Bleeding and management of coagulopathy. *J Thorac Cardiovasc Surg* 142:662–667, 2011.)

Residual heparin effect should be assessed on admission to the ICU because the heparin effect is usually seen early in the postoperative course (the half-life of heparin is approximately 1 hour).¹⁴⁷ The specific treatment is administration of protamine sulfate (25 mg doses are given, and the ACT is repeated).¹⁴⁸ Consideration of CPB time and dosages of heparin and protamine must guide decision making.

Randomized data have shown that higher heparin dosages using point-of-care, patient-specific monitoring during CPB reduce transfusion compared with empiric dosages. Higher stable heparin concentrations result in decreased thrombin generation, inhibition of clot-bound thrombin, and preserved platelet function after prolonged (>2 hr) CPB.^{149,150} In addition, heparin reversal with empiric half-dose or protamine titration methods (protamine-to-heparin ratio < 1) may also decrease chest tube drainage and transfusion requirements.¹⁵⁰

Thrombocytopenia

Thrombocytopenia results from destruction of platelets during CPB or from consumption.^{151,152} In the absence of other abnormalities, treatment is platelet transfusion. Notably, if a patient is not actively bleeding, thrombocytopenia is generally not corrected with transfusion, because the platelet level usually normalizes spontaneously over the next few days. Among the many patients maintained preoperatively on heparin, persistent postoperative thrombocytopenia may be induced by the presence of heparin-dependent antibodies. In this setting, resulting thromboembolic events and significant bleeding have been observed.¹⁵³ Diagnosis of heparin-induced thrombocytopenia can be made with heparin-platelet aggregation testing and a platelet factor intravenous assay to confirm the presence of antibodies in vitro. All heparin should be discontinued promptly in these patients.

Thrombasthenia

In patients with thrombasthenia, the platelet count is normal but clot formation is inadequate. This remains a significant problem in the postcardiac surgical patient.¹⁴³ It can be documented by measuring the thromboelastogram (TEG).¹⁵⁴ Qualitative defects in platelet function result from CPB^{143,155} or from antiplatelet therapy.¹⁵⁶ Aspirin and clopidogrel irreversibly affect platelet function, the life span of which is 6 to 7 days. Therefore, a single dose administered within the 7 days before the operation diminishes platelet function, which can result in a significant increase in bleeding complication and transfusion requirements.^{157,158} Current guidelines from the American College of Cardiology and American Heart Association (ACC/AHA) and Society of Thoracic Surgeons (STS) recommend discontinuing ADP inhibitors 5 to 7 days before cardiac surgery, if possible.^{150,159}

Specific Factor Deficiencies

Specific factor deficiencies are usually manifested by elevation of the PT or the PTT. Abnormalities may result from a specific genetic disorder, liver disease, prior

Coumadin therapy, hemodilution, or disseminated intravascular coagulation (DIC). These disorders are generally treated by specific factor therapy, fresh-frozen plasma, or cryoprecipitate.

Management of Bleeding

Specific treatment consists of blood component therapy based on an accurate diagnosis and an understanding of the changes that occur during CPB. Guidelines for transfusion support as well as management of postoperative patients with significant hemorrhage have been suggested.¹⁵⁰ The observed rate of bleeding must be correlated with its character (the initial bleeding rate may reflect drainage of sequestered blood or irrigation fluid) and hemodynamic effect (ineffective drainage may lead to an underestimate of ongoing intravascular depletion). The quality of blood clotting may be effectively estimated by close observation of the drainage tube contents and manual manipulation of the tubes. Large amounts of clot that repeatedly obstruct the tubes indicate a surgical source of bleeding. Nonclotting, freely draining blood or the presence of loosely organized clot indicates that a state of coagulopathy exists.

Bleeding at a rate of more than 200 mL/hr requires immediate action to search for and correct the underlying cause. Delays in laboratory testing frequently preclude accurate and timely diagnosis. The single most practical treatment is to administer platelet concentrate, which is often effective despite an apparently adequate platelet count when the platelets are dysfunctional. Fresh-frozen plasma fraction is used to replenish coagulation factors manifested as a prolongation of the PT for PTT. Available sources of fibrinogen for supplementation include fresh-frozen plasma, cryoprecipitate, and fibrinogen concentrates. With appropriate treatment of coagulation deficiencies, coagulopathy usually resolves within a few hours. Bleeding usually diminishes to modest levels (50 to 100 mL/hr) within 4 hours, and rarely is the total amount drained more than 1 liter.

Reoccurrence of high drainage rates should be addressed immediately, despite the fact that sudden drainage of sequestered blood is common when the patient is repositioned. It is not uncommon for a new bleeding site to develop with clot lysis or after a brief episode of severe hypertension. A common scenario is initial bleeding at rates of 150 to 250 mL/hr, followed by alternating periods of inconsequential drainage and substantial drainage. This often indicates surgically correctable bleeding, with a large burden of intramediastinal clot and ineffective tube drainage resulting from clot obstruction. When the bleeding issue is not resolved within a few hours, a second chest radiograph should be obtained to ensure that mediastinal and pleural drainage has been effective.

Massive transfusion coagulopathy that occurs in cardiothoracic trauma, complex aortic surgery, and other massive bleeding patients should prompt consideration of a transfusion protocol involving fixed ratios of fresh-frozen plasma, platelets, and red blood cells. Algorithms outlining empiric treatment are usually developed with input from surgeons and blood bank directors. While

there is certainly no substitute for meticulous surgical technique, the cause of unusually high transfusion requirement is often multifactorial after complex aortic surgery, referable to a multitude of interrelated factors including interference with the vascular integrity, surgical dissection, deep hypothermia for circulatory arrest, ischemia and reperfusion, dilution of coagulation factors from large-volume fluid resuscitation, transient need for heparinization, and the use of CPB. Deep hypothermia for neuroprotection in thoracic aortic surgery slows coagulation cascade activity, reduces coagulation factor synthesis, increases fibrinolysis, decreases platelet count, and impairs platelet function. The prosthetic grafts used for aortic repair consume platelets and other factors, and aortic disease itself may also predispose to coagulopathy via the exposure of tissue factor and other mechanisms.

The major side effects of postoperative bleeding are volume loss and retention of clotted blood in the mediastinum. Nonspecific therapy consists of continuous, adequate volume replacement, maintenance of free drainage, and prevention of hypothermia. Hypothermia has a generalized anticoagulant effect that increases PT and PTT measurements in direct accordance with the degree of temperature change.¹⁶⁰ Mechanical means should be used to maintain mediastinal chest tube patency, including (1) application of suction, (2) stripping and milking of chest tubes (note that mechanical stripping of chest tubes can create negative pressures as high as 1500 mm Hg and can be potentially damaging to entrapped tissues), and (3) if necessary, Fogarty catheter thrombectomy of the mediastinal tubes. Sterile endotracheal tube suction catheters may also be used for thrombectomy of mediastinal tubes with great care to avoid passing any catheter beyond the length of the mediastinal chest tube. Catheter thrombectomy usually precedes reoperation and may relieve significant tamponade.

Other nonspecific measures include strict control of blood pressure and induction of mild controlled hypotension, which can markedly diminish bleeding rate. However, afterload reduction can be particularly dangerous in the hypovolemic patient with ongoing blood loss and early cardiac tamponade. Levels of PEEP in the range of 10 to 12 cm H₂O have been suggested as a means to reduce postoperative bleeding.¹⁶¹ The efficacy of PEEP in slowing postoperative bleeding remains controversial,¹⁵⁰ and acute reduction in preload with this level of PEEP is potentially dangerous.¹⁶²

Crystalloid and Colloid Volume Resuscitation

Crystalloid solutions may be provided as normal saline or lactated Ringer solution. Colloid solutions include the following:

1. Serum albumin as a 25% solution. Serum albumin in its 25% solution must recruit extravascular fluid to result in effective volume replacement.
2. Plasma protein fraction (Plasmanate) as a 5% protein solution containing both albumin and alpha and beta globulins. Plasmanate may cause a paradoxical hypotension attributed to the use of acetate,

present as a buffer, or may cause the presence of Hageman-factor fragments.^{163,164}

3. Hydroxyethyl starch (Hetastarch). Hetastarch provides plasma volume expansion for more than 24 hours and may be safely used to a total volume of 1.5 liters. Because Hetastarch has a chemical composition similar to that of dextran, associated urticarial and anaphylactoid reactions may occur. There are continuing concerns regarding the effect of Hetastarch solutions on blood coagulation.¹⁶⁵

The choice of colloid versus crystalloid must be made on an individual basis. The largest randomized prospective clinical trial available comparing saline to albumin in a diverse group of intensive care patients was unable to demonstrate any difference in numbers of days spent in the ICU, days spent in the hospital, days of mechanical therapy, or days of renal-replacement therapy.¹⁶⁶

Blood Conservation

Blood conservation requires a programmatic approach but is essential to improving patient outcomes. There is level I evidence that blood and blood products negatively influence outcome, expose patients to viral and bacterial infection, and may reduce host resistance to infection.¹⁴¹ In addition to these risks, blood transfusions are expensive and blood supply is scarce. As a result, blood use and transfusion outcomes are under renewed scrutiny by health care institutions, regulatory agencies, and accreditation organizations. The tolerance of a reduced hematocrit in the postoperative cardiac patient is an important component in the avoidance of blood transfusion. In the past, a hematocrit greater than 0.30 was believed to be important⁴³; however, this teaching has changed with the findings of recent clinical trials showing that restrictive transfusion practices are equivalent or better than liberal transfusion practices. Guidelines have been published by the National Institutes of Health, and more recently by the STS, stating that it is reasonable to transfuse blood in postoperative patients with a hemoglobin of less than 7 g/dL.¹⁶⁷ It is reasonable to not transfuse a postoperative patient who has a hemoglobin of 7 g/dL or greater based on the patient's clinical situation and if end-organ ischemia is not demonstrated. In addition, supplements with oral iron therapy, and occasionally folic acid, may restore normal hematocrit within 6 weeks of surgery.

Pharmacologic Considerations

A variety of pharmacologic agents represent important tools in the recovery of patients following cardiac surgery. Clinical evidence of an association between the incorporation of non-transfusion-based strategies for treating coagulopathy and decreased use of blood products is increasing.

Desmopressin

Desmopressin (1-deamino-8-D-arginine vasopressin, DDAVP), a synthetic analog of L-arginine vasopressin, has been shown to improve platelet function and reduce hemorrhage in a variety of clinical disorders. DDAVP

appears to act by increasing the concentration of von Willebrand factor, an important mediator of platelet adhesion. No consensus exists regarding the prophylactic use of DDAVP.¹⁶⁸ However, patients who have ongoing hemorrhage may be considered for administration of 3 µg/kg given over 15 minutes. Among patients with severe aortic stenosis, DDAVP may help reduce perioperative blood loss given the common finding of acquired von Willebrand syndrome in this population.¹⁶⁹ A similar condition of acquired von Willebrand syndrome is also known to exist among patients with ventricular assist devices.

Aprotinin

Aprotinin is a nonspecific protease inhibitor extracted from bovine lung and has been used as a method of reducing postoperative mediastinal bleeding. Administration of aprotinin before CPB can preserve platelet function otherwise lost during CPB.¹⁷⁰ Aprotinin is a serine protease inhibitor of multiple enzymes including plasmin, trypsin, kallikrein, chymotrypsin, activated protein C, and thrombin. The beneficial effects of aprotinin are mediated by its antifibrinolytic, antithrombotic, and anti-inflammatory effects. More than 70 randomized controlled trials including from 20 to 796 patients showed the efficacy of aprotinin in limiting the need for allogeneic transfusions in patients undergoing cardiac surgery. However, three contemporary trials called into question the safety of aprotinin,¹⁷¹⁻¹⁷³ and these findings, combined with the early termination of the Blood Conservation Using Antifibrinolytics in a Randomized Trial (BART) because of an increase in all-cause 30-day mortality in patients receiving aprotinin, led to suspension of the marketing and distribution of aprotinin in the United States.¹⁷⁴

ε-Aminocaproic Acid and Tranexamic Acid

ε-Aminocaproic acid (EACA) and tranexamic acid (TXA) are two synthetic antifibrinolytic agents in common use in modern cardiac surgery. These agents are lysine analogs and competitively inhibit the activation of plasminogen to plasmin. Prophylactic antifibrinolytic therapy with intraoperative and postoperative administration of these agents is now commonplace. Most of the clinical efficacy data are of TXA, with several trials reporting a decrease in bleeding complications with TXA use. However, several reports have noted seizures associated with TXA, believed to be a result of the ability of TXA to block gamma-aminobutyric acid (GABA) receptors in the frontal cortex.¹⁷⁵

Recombinant Activated Factor VII

Activated coagulation factor VII is a vitamin K–dependent glycoprotein that promotes hemostasis by activating the extrinsic pathway of the coagulation cascade. As a new hemostatic agent, recombinant factor VIIa (rFVIIa) is increasingly being used off-label in cardiac surgery for the treatment of severe coagulopathy-related bleeding that is not responsive to typical factor replacement.

rFVIIa in the treatment of bleeding following cardiac surgery is commonly administered at doses up to 1000 times the physiologic level and has a half-life of approximately 2.5 hours.¹⁷⁶ Although rFVIIa acts by generation of thrombin on thrombin-activated platelets and therefore is theoretically localized to sites of vessel-wall injury, systemic activation of coagulation may occur. As such, the primary concern surrounding the use of rFVIIa is its potential as a hemostatic agent to induce thromboembolic events.¹⁷⁷ Nonetheless, clinical studies continue to emerge indicating rFVIIa administration in appropriately selected patients may correct coagulopathy early in the course of refractory blood loss associated with cardiac surgery, although appropriately powered randomized studies are necessary to confirm the safety and efficacy of this approach.¹⁷⁸

NEUROLOGIC COMPLICATIONS

Neurologic dysfunction is a major cause of death and disability after cardiac surgery. Neurologic injury encompasses a spectrum of disorders such as stroke, encephalopathy, and cognitive dysfunction. Recent analysis of annual data from the Society of Thoracic Surgeons National Cardiac Database reveals a peak stroke rate for CABG of 1.7% in the year 2000. The stroke rate falls to approximately 1.2% in 2008 and has remained constant since then. Clinical variables found to increase risk include neurologic disease, age, hypertension, female sex, atherosclerosis of the ascending aorta, and diabetes.¹⁷⁹

The cause of neurologic dysfunction after cardiac surgery is multifactorial and is the focus of active research and quality improvement initiatives.¹⁸⁰ Causal factors for neurologic dysfunction include (1) particulate and gaseous emboli from the CPB apparatus, (2) macroemboli from aortic manipulation, (3) macroemboli from the extracranial cerebral vasculature, (4) regional malperfusion resulting from extracranial vascular obstruction, (5) regional malperfusion resulting from generalized hypoperfusion during CPB (watershed cerebral infarction), (6) regional malperfusion resulting from impaired cerebral autoregulation (more prevalent in diabetics), and (7) generalized central nervous system edema after CPB.

Major stroke is often caused by atherosclerotic emboli originating in the aorta; more subtle neuropsychologic deficits may be caused by microemboli.¹⁸¹ Autopsy studies in patients who have undergone CPB have detected microscopic emboli, composed primarily of lipid, dispersed in the cerebral microvasculature.¹⁸² The arterial line filters that have become standard equipment on most CPB circuits do not eliminate the microscopic lipid deposit that enters shed blood in the mediastinum (Fig. 60-13).¹⁸³ Moreover, the use of cardiotomy suction to recover shed blood in combination with CPB results in significantly more microembolic events relative to CPB alone. Other studies have introduced the possibility that processing shed blood by washing and centrifugation with a cell-saver device before return to the CPB circuit may reduce these events.¹⁸⁴

Given the mechanism of neurocognitive injury with cardiac surgery involving CPB (i.e., emboli from

FIGURE 60-13 ■ Debris commonly found on in-line arterial filters. Scanning electron micrographs of 40-micron arterial line filters after clinically uneventful cardiopulmonary bypass. **A**, Crystalline material can be seen embedded in the filter mesh with an adherent mass of fibrinous material incorporating erythrocytes. **B**, Particle measuring approximately $80 \times 600 \mu\text{m}$, thought to be spalled silicone rubber. **C**, Exogenous, organic fiber. **D**, Complex crystalline deposit. cannulation and fatty or gaseous microemboli that are not filtered with standard CPB techniques), OPCAB has been suggested as a potential avenue to improve neurocognitive outcomes. There is clear evidence that there are fewer microemboli to the brain in patients having OPCAB than in those having conventional on-pump revascularization.¹⁸⁵ The significance of fewer microembolization events, however, is not entirely clear. A large prospective randomized clinical trial failed to show any difference in cognitive decline between off- and on-pump revascularization after 5 years of follow-up.¹⁸⁶ Furthermore, a four-arm prospective cohort study compared (1) patients who had on-pump coronary surgery, (2) patients who had off-pump coronary surgery, (3) patients with medically managed coronary disease, and (4) patients without coronary disease. There was no difference in cognitive outcome between all groups with coronary disease at 3 years, whether they had conventional CPB, OPCAB, or medical management. The patients without coronary disease had significantly higher cognitive performance than any of the other three groups at all time points through 6 years.¹⁸⁷ These results suggest that coronary artery disease may be a surrogate marker for occult cerebrovascular disease and these patients are at increased risk for future neurologic dysfunction independent of CABG.

Other factors that contribute to neurologic dysfunction, particularly in older adults, include (1) “ICU psychosis” related to stress, environmental impact, and loss of ability to compensate to surroundings; (2) sleep deprivation; (3) adverse drug reactions; and (4) revelation of previously well-compensated mild dementia.

Often, focal deficits are completely reversible if the patient is appropriately managed. The maintenance of adequate perfusion and oxygen delivery is critical to recovery. Cerebral blood flow is improved by head elevation to reduce edema and hyperventilation to provide moderate hypocapnia. General support includes protection of the patient’s airway, management of pulmonary secretions, avoidance of pulmonary aspiration, and provision of nutrition. Because dramatic recovery is frequent, patient and family support should be aggressive in the first few days after surgery unless a definitive mortal injury can be defined.

Delirium is known to be a common condition (3% to 72% depending on method of assessment) in the ICU following adult cardiac surgery. Postoperative delirium is associated with increased length of stay, complications, and higher mortality. Prevention focuses on frequent orientation and noise reduction, early mobilization out of bed, and having a familiar face at the bedside. Delirium may be classified as hyperactive, hypoactive, or mixed.

For each type, management includes a thoughtful search for and treatment of underlying causes of the delirium, nonpharmacologic measures, and symptomatic drug therapy. The patient's medication list should be critically reviewed, and any drugs with anticholinergic side effects should be tapered. Benzodiazepines are GABA agonists and may therefore decrease consciousness and REM sleep—tapering these agents may alleviate delirium. Haloperidol remains the recommended agent for severe agitation, given in doses of 0.5 to 5 mg. The α_2 -adrenergic agonists clonidine and dexmedetomidine may also be useful in those patients with sympathetic overactivity. Suspected signs of delirium should not be ignored and instead promptly investigated and treated.¹⁸⁸

INFECTION

The incidence of fever decreases exponentially throughout the postoperative course. Fevers not related to infectious causes are most commonly low grade ($<38.9^\circ\text{C}$, rectal), and most resolve before the 15th postoperative day. A temperature higher than 38.9°C at any time in the postoperative course is more likely to be related to a specific infection. The presence or absence of leukocytosis has not been helpful in this differentiation.¹⁸⁹ Historically, from days 4 to 9 postoperatively, approximately 25% of fevers are related to serious infection.¹⁹⁰

When infection is suspected, aggressive evaluation is indicated. Aerobic and anaerobic cultures of blood, urine, sputum, and abnormal fluid collections are mandatory and should precede broad-spectrum antibiotic coverage. Indwelling catheters should be considered potential infectious sites. Evidence-based infection control practices help to prevent serious infections stemming from catheter use.¹⁹¹

Soft tissue infection is most commonly caused by *Staphylococcus aureus*, although *Staphylococcus epidermidis* has emerged as an important pathogen. *Pseudomonas* and other gram-negative infections become more common when the intensive-care stay exceeds 7 days and in patients receiving broad-spectrum antibiotic therapy.¹⁹² Prolonged intensive care and antibiotic use can also cause systemic fungal infections and loss of the gastric mucosal barrier.¹⁶² These infections are particularly difficult to diagnose because of their protean manifestations. Mediastinitis is of particular concern in all cardiac surgical patients and can be cryptic in presentation. The incidence has been reported to range from 0.8% to 1.86%.¹⁹³ The risk factors associated with mediastinitis have been determined (Table 60-2), as has a negative impact on long-term survival independent of other preoperative risk factors (Fig. 60-14). Sternal and mediastinal infections must be differentiated from simple subcutaneous fat necrosis, sterile sternal dehiscence, and the post-pericardiotomy syndrome.

Deep sternal infections and mediastinitis are commonly associated with systemic symptoms (fever, leukocytosis), localized tenderness, severe persistent chest pain, and sternal instability.¹⁹³ Chest film, computed tomography, and indium-111 leucocyte scanning can be used to confirm the clinical diagnosis. Initial treatment

consists of operative wound exploration, débridement, and drainage.¹⁹⁴ Diminished morbidity has been reported with pectoral flap or omental flap closure.^{195,196} Flap closure may be performed as a primary procedure with accompanying sternal débridement¹⁹⁷ or as a staged procedure with sternal débridement followed by closure in 3 or 4 days.^{195,198} A recent cohort study demonstrated similar survival rates of patients with mediastinitis treated with vacuum-assisted closure and patients without mediastinitis who underwent coronary revascularization alone, suggesting that vacuum-assisted closure may be as effective as flap closure.¹⁹⁹

Soft tissue infections involving saphenous vein harvest, although usually minor, represent a significant source of morbidity after coronary revascularization. This complication has been reported to occur in 3% of patients and is more common in the thigh harvest site. They are best prevented by careful selection of harvest sites and the use of meticulous surgical technique. Endoscopic vein harvest

FIGURE 60-14 ■ **A**, Unadjusted Kaplan-Meier survival plot is shown for patients with and without mediastinitis after coronary artery bypass graft (CABG) surgery. The numbers of surviving patients in each group at 0, 1, and 2 years after surgery are shown at the bottom of the graph. **B**, Variable-adjusted survival plot after CABG surgery. Kaplan-Meier survival plot is adjusted for age, ejection fraction, extent of coronary artery disease, peripheral vascular disease, cerebrovascular disease, recent myocardial infarction, angina status, and mitral insufficiency. appears to have made a favorable impact on the rate of this complication.²⁰⁰ Most saphenous vein harvest site infections may be treated effectively by simple drainage, dressing changes, and prescription of antibiotics. However, in severe cases, wide débridement and skin grafting may be necessary.

SPECIFIC THORACIC INJURIES

LONG-TERM OUTCOMES

SUMMARY

In contrast to set-piece wars of the past, modern warfare is characterized by a “nonlinear” battlefield with intermittent engagements of an elusive enemy.¹ Soldiers wear advanced protective gear including helmets, ballistic eyewear, ceramic torso plates, and Kevlar neck, arm, and groin pieces. Even transport vehicles are surrounded in ballistic armor. In addition to typical weapons such as high-velocity automatic rifles, mortars, and grenades, high-energy improvised explosive devices (IEDs) are used. The protective gear of modern warfare has significantly reduced injury rates among deployed soldiers; however, direct strikes that find gaps in the body armor or indirect fire attacks on bases, where soldiers without protective gear are targeted, can result in highly destructive injuries.

Combat medical care has also evolved significantly in recent times.^{2,3} There is a renewed emphasis on combat medic training to provide lifesaving care under fire; in-theater transport care is now more commonly provided by highly trained medics and even midlevel practitioners and physicians; and advanced surgical care has been pushed closer to combat activities as part of the in-theater trauma system. Although hemorrhage remains the most common cause of prehospital death,⁴ soldiers with historically nonsurvivable injuries are now arriving alive at forward facilities. As a result of these many advances, and despite the injury severity of our combat wounded reaching historically high levels, the case fatality rate is at an all-time low of less than 10%.⁵

Thoracic injuries still represent a significant proportion of combat wounds, including both blunt and penetrating injuries. Ballistic vests afford significant protection to our soldiers, converting potentially lethal injuries into minor contusions in many cases (Fig. 61-1). However, significant chest injuries still occur in 5% to 10% of casualties (Fig. 61-2). These patients require advanced

management by multiple teams of providers in several medical facilities over many thousands of miles. This chapter describes the historical context of this management strategy and the current approach to complex thoracic injuries in multiply injured combat casualties.

A BRIEF HISTORY OF WAR-RELATED CHEST WOUNDS

Prior to World War I, surgical intervention on a combat chest wound was rare, and mortality from these injuries was over 60% (Fig. 61-3). The concept of negative intrathoracic pressure was first demonstrated by Ludwig in 1847 and then by Aron in 1900.⁶ However, in the early 1900s, the nuances of thoracic physiology and its clinical implications remained poorly understood. Indeed, the significance of negative intrathoracic pressure was not fully appreciated until 1923.⁶

It was in this era that Dr. Evarts Graham was appointed to the Surgeon General’s Empyema Commission.⁶ This famous commission was tasked with determining the optimal treatment for complex parapneumonic effusion and empyema resulting from streptococcal pneumonia, which had spread among enlisted troops afflicted by the influenza pandemics of 1917 and 1918 and was associated with a mortality of up to 90% in some of the camps. The commission determined that, in contrast to pneumococcal empyema, which responded well to open drainage, the preferred treatment in patients with streptococcal infections was repeated thoracentesis followed by delayed open drainage. This new approach reduced the mortality from streptococcal empyema to less than 5%. Graham was inspired to further explore respiratory mechanics and to confirm his clinical observations in the laboratory by developing an animal model of streptococcal empyema.

FIGURE 61-1 ■ Two different soldiers who suffered a direct hit to the anterior plate of their body armor. The strike plate absorbed the energy of the blast and prevented a devastating penetrating injury to the chest. These patients suffered minor chest wall contusions. (A, Courtesy Col David L. Smith, MD, USAF, Retired; B, From McNeil JD, Pratt JW: Combat casualty care in an Air Force theater hospital: perspectives of recently deployed cardiothoracic surgeons. *Semin Thorac Cardiovasc Surg* 20(1):78–84, 2008, Figure 5, with permission.)

FIGURE 61-2 ■ A, Destructive injury of the chest characteristic of combat injuries involving high-velocity projectiles. B, The avulsed latissimus was reattached to the posterior chest wall.

Through this work, he determined conclusively that the mediastinum was, in fact, not a fixed structure as it had been viewed previous to his work and that patients with streptococcal empyema subjected to early thoracotomy very likely died of the open pneumothorax in the setting of minimal respiratory reserve.

Dr. Graham continued to exert his influence in World War II by ensuring that thoracic-trained surgeons were appointed to the Second Auxiliary Surgical Group, which then formed the first Thoracic Surgery Center in Tunisia in 1943. Among these surgeons was Dr. Lyman Brewer who, along with Dr. Edward Churchill, shaped the approach to managing combat thoracic injuries and postinjury empyema.⁷ World War II saw a significant increase in the use of formal thoracotomy for the management of combat wounds; in fact, in many cases, thoracotomy was being overused. Brewer, with Churchill's support, called for a more measured approach and outlined the indications for thoracotomy⁷:

1. Continued bleeding (severe)
2. "Traumatic" thoracotomy (large sucking wound)
3. Thoracoabdominal wound
4. Miscellaneous
 - a. Heart or esophagus repair
 - b. Trachea or bronchus repair
 - c. Foreign body larger than 2 cm

Interestingly, these indications for thoracotomy largely apply even in modern combat casualty care.

Routine use of tube thoracostomy was not widely accepted during World War II.⁸ Although the thoracic drainage system developed by Lilienthal in 1926 was available in WWII, intermittent thoracentesis was favored for the management of pleural effusions and hemothorax.

The modern three-chamber drainage system was described in 1952 by Howe, and the technique of tube

FIGURE 61-3 ■ Mortality from combat thoracic injuries over time. OEF/OIF, Operation Enduring Freedom/Operation Iraqi Freedom; PCN, penicillin; PPV, positive pressure ventilation. (From Ivey KM, White CE, Wallum TE, et al: Thoracic injuries in US combat casualties: a 10-year review of Operation Enduring Freedom and Iraqi Freedom. *J Trauma Acute Care Surg* 73:S514–S519, 2012, Figure 1, with permission.)

thoracostomy was being widely used in civilian trauma.⁹ However, repeated thoracentesis remained the primary management strategy for traumatic pneumothorax and hemothorax along with instillation of antibiotics into the thoracic cavity even through the Korean War.⁸ It was not until multiple civilian centers reported the usefulness of tube thoracostomy in thoracic trauma in the 1960s that this approach became the mainstay for both primary management of simple intrathoracic problems like pneumothorax and postoperative management following major thoracotomy for trauma.

Although positive pressure ventilation with a facemask was first used by Brewer as early as 1944 for the management of posttraumatic pulmonary edema (i.e., modern-day acute respiratory distress syndrome),^{7,10,11} it was not until the development of plastic endotracheal tubes, rapid blood gas analysis, and the polio epidemic of 1952 (negative pressure ventilation) that mechanical ventilation became a routine part of critical care management of patients with severe thoracic trauma. All of these capabilities are now readily available, even in the most austere combat casualty care environments. In addition to these routine management tools, modern combat casualty care has also advanced the concepts of damage control surgery, damage control resuscitation, and critical care air transport to maximize survival of combat casualties as summarized in the remainder of this chapter.

MODERN PRINCIPLES OF COMBAT CASUALTY CARE

One of the greatest advances in modern combat casualty care has been the establishment of a formal trauma system for the care of our wounded soldiers.¹² In November 2004, the Joint Theater Trauma System (JTTS) was created to apply lessons learned from civilian trauma systems across the United States to the combat theaters in Iraq and Afghanistan. The fundamental aspects of this system included the continual presence of a senior trauma surgeon—the theater trauma director—and a cadre of nurse specialists trained in performance improvement and data collection.

Now in its 10th year of operation, this team is responsible for educating deployed medical units on the most current clinical practice guidelines (CPGs) (available at

http://www.usaisr.amedd.army.mil/clinical_practice_guidelines.html). This team also conducts a weekly performance-improvement case-based teleconference that spans the globe. Finally, this team and its parent organization, the Joint Trauma System (JTS), track outcomes over time and advocate for policy and practice changes in order to continually improve the care that is delivered. This systematic approach stands in stark contrast to the first Gulf War, during which the lack of an organized trauma system resulted in numerous mistakes in combat casualty care.¹³ As the result of almost a decade of work, the value of this is evidenced by the lowest case fatality rate among combat casualties in all of recorded history.⁵

It is interesting to note the current deployment patterns for surgeons by specialty and military branch. Currently, all three branches have cardiothoracic surgeons on active duty and in the reserves. These surgeons function primarily as general surgeons when deployed. In one report, 79% of cases performed by cardiothoracic surgeons were general surgical cases, whereas 21% were index thoracic or major vascular procedures (Table 61-1).¹⁴ The U.S. Army does not differentiate surgical subspecialists for deployment purposes. Cardiothoracic surgeons, trauma surgeons, vascular surgeons, colorectal surgeons, surgical oncologists, pediatric surgeons, and laparoscopic surgeons all deploy as general surgeons. This is true of both active duty and reserve surgeons in the army. During the height of the operational tempo, the U.S. Air Force deployed both cardiothoracic and vascular surgeons specifically to the aeromedical evacuation hubs in Iraq and Afghanistan to ensure definitive vascular reconstruction was performed prior to long-range transport in patients with major vascular injuries in the torso or extremities.¹⁴ In at least one case, the deployed cardiothoracic surgeon also functioned as the “trauma czar,” who was responsible for ensuring the stability and readiness of each casualty prior to evacuation. Similarly, the U.S. Navy has deployed at least one cardiothoracic surgeon as the theater trauma director, who is tasked with supervising the research team while also ensuring uniformity across the various treatment facilities in theater and adherence to the CPGs as much as possible. Consequently, maintaining a broad skill set is vitally important for all military surgeons regardless of their specialty.¹⁵ Cardiothoracic surgeons, as a result of comprehensive

training in general surgery, thoracic surgery, vascular surgery, and critical care, are uniquely prepared to provide care to the multiply injured combat casualty.

By far, most potentially preventable combat deaths result from hemorrhage. This finding is true of deaths prehospital (killed in action [KIA]) and those patients who arrive at a medical facility with detectable vital signs but then go on to expire (died of wounds [DOW]).^{4,16} Consequently, great emphasis has been placed on identifying new means of controlling both compressible (i.e., extremity) and noncompressible hemorrhage using hemostatic dressings,¹⁷ inflatable polymers,¹⁸ and endo-aortic balloon placement.^{19–21}

Other potentially preventable causes of death include airway obstruction, tension pneumothorax, and multiorgan failure. Airway management has been addressed by teaching combat medics placement of a cricothyroidotomy in tactical situations.²² For tension pneumothorax, the traditional anterior needle decompression approach has received scrutiny because postmortem studies have shown that often the needle does not enter the pleural space.²³ This finding has generated interest in identifying alternative approaches such as the lateral placement technique and modification of existing devices such as a Veress needle, which can be used if tension pneumothorax is suspected.^{24–26} Finally, multisystem organ failure deaths are being addressed by introducing advanced organ support modalities like renal replacement therapy (RRT) and extracorporeal membrane oxygenation (ECMO) further forward in the combat theater (Fig. 61-4).²⁷

Increased attention has also been paid to the care delivered en route from point of injury to a military treatment facility (MTF). For the most critically injured soldiers, dispatching transport teams with flight paramedics who have a higher level of training has been shown to improve survival.²⁸ The United Kingdom has taken this one step further and has created a team with flight nurses and physicians, who recover casualties from point of injury. This so-called medical emergency response team (MERT) has also proven beneficial for the most severely injured casualties.²⁹

In a mature combat theater, combat casualties typically pass through multiple levels of care prior to evacuation.³⁰ Within the combat theater, there are three levels of MTFs, ranging from an aid station with no surgical capability (level I) to a site with far forward general and orthopedic surgeons (level II) and finally an austere

FIGURE 61-4 ■ A combat casualty with severe respiratory failure managed with venovenous extracorporeal membrane oxygenation (VV ECMO). (Courtesy MAJ Matthew Bacchetta, MD.)

hospital-type facility that has more advanced imaging capabilities and more surgical subspecialties (level III).³¹ However, movement through this system is not always a strictly linear process. The JTS has been instrumental in advocating that a balance be struck between expedient transport and transport to a location where the patient's problem can be managed. For example, a patient with an open skull fracture would typically be moved to a level III facility with a neurosurgeon, if at all possible, and a patient with an open chest wound and shock would be taken to either a level II or level III facility—whichever is closer—rather than a level I facility.

All combat casualties within the theater who cannot return to duty eventually filter into the level III facility designated as the aeromedical hub for long-range evacuation to a level IV facility (Landstuhl Regional Medical Center in Germany in this case) and then on to a level V facility in the United States where they receive definitive care. Modern ICU-level care can be provided in transport by a Critical Care Air Transport Team (CCATT); however, the patient should be stabilized or at least “stabilizing” prior to transport.^{32,33} For patients with thoracic trauma, this typically means that any intrathoracic (i.e., noncompressible) hemorrhage has been controlled, any air leaks are managed with tube thoracostomy that is well secured to the patient, any coagulopathy has been

FIGURE 61-5 ■ A combat casualty managed with independent lung ventilation. (Courtesy Lt. Col. Phillip Mason, MD.)

FIGURE 61-6 ■ Extracorporeal membrane oxygenation used to transport a combat casualty with severe early respiratory failure. (Courtesy LTC Sandra Wanek, MD.)

reversed, and the patient is on stable and moderate to low ventilator settings or even extubated. In the vast majority of cases, these requirements can be met during a short stay in the level III facility. However, in some cases, advanced maneuvers such as independent lung ventilation (Fig. 61-5), inhaled pulmonary vasodilators, rescue ventilator modalities, or even ECMO are required to ensure safe transport.²⁷ The need for such interventions, which are beyond the standard CCATT capabilities, was first recognized in 2005 and resulted in the establishment of the Acute Lung Rescue Team (ALRT) based at the level IV facility.^{34,35} As of 2010, this team had performed 24 complex patient transports, and as of 2011, 10 U.S. patients had been transported with either pumpless lung support or full ECMO with a 90% survival (Fig. 61-6).^{36,37}

DAMAGE CONTROL RESUSCITATION AND SURGERY

Modern combat casualty trauma care has fully embraced the principles of damage control resuscitation (DCR) and damage control surgery. This approach requires rapid

TABLE 61-2 Predictors of MT Using Physiologic Parameters and Lab Values from the Trauma Bay

Predictor	OR (95% CI) for MT	Sensitivity	Specificity
INR > 1.5	2.5 (1.7-3.7)	37	87
SBP < 90 mm Hg	1.7 (1.2-2.5)	44	76
Hb < 11 g/dL	1.8 (1.3-2.6)	54	70
BD ≥ 6	2.0 (1.4-2.9)	75	51
HR ≥ 120 bpm	1.2 (0.8-1.7)	42	77
Penetrating	0.9 (0.6-1.3)	39	72
FAST (+)	1.8 (1.2-2.5)	36	65
Any two of the above	3.9 (2.6-5.8)	85	41

Bold signifies statistical significance.

BD, Base deficit; bpm, beats per minute; CI, confidence interval;

FAST, focused assessment with sonography for trauma;

Hb, hemoglobin; HR, heart rate; INR, international normalized ratio; MT, massive transfusion; OR, odds ratio; SBP, systolic blood pressure.

From Callcut RA, Cotton BA, Muskat P, et al: Defining when to initiate massive transfusion: a validation study of individual massive transfusion triggers in PROMMTT patients. *J Trauma Acute Care Surg* 74(1):59-65, 67-68; discussion 66-67, 2013.

recognition of the patient in shock who has already developed, or who is at risk for developing, the deadly triad of hypothermia, coagulopathy, and acidosis. In such patients, reversible causes of shock are rapidly excluded (e.g., tension pneumothorax) and so-called DCR is rapidly initiated en route to the operating room. This includes initiation of a massive transfusion (MT) protocol with balanced transfusion of hemostatic products (plasma, platelets, fresh whole blood, and/or cryoprecipitate) and red blood cells, avoidance of crystalloid, avoidance of hypertension, avoidance of hypothermia, and consideration of hemostatic adjuncts (e.g., tranexamic acid).^{38,39}

One significant challenge in this area is prospectively identifying patients who may need DCR. In both standard trauma resuscitations and multiple casualty events, finding those patients with occult life-threatening injuries who have bled significantly or who have the potential to bleed has been greatly simplified with the development of simple decision tools such as the Assessment of Blood Consumption (ABC)⁴⁰ or the Individual Transfusion Trigger (ITT). The predictors for MT most commonly used are listed in Table 61-2. A recent study using prospective data collected in 297 MT patients as part of the Prospective Observational Multicenter Major Trauma Transfusion (PROMMTT) study identified an INR greater than 1.5 as the strongest individual predictor for MT (adjusted OR, 2.5; 95% confidence interval, 1.7-3.7), and any two predictors present identified patients managed with MT with an 85% sensitivity (OR, 3.9; 95% confidence interval, 2.6-5.8).⁴¹

In the patient with multiple penetrating injuries, a high index of suspicion for simple or tension pneumothorax and cardiac injury with tamponade must be maintained, particularly in patients presenting with tachycardia and hypotension. Focused assessment with sonography for trauma (FAST) examination can be rapidly performed to determine if there is pericardial fluid, and it can be

repeated if a patient's clinical condition deteriorates following an initially negative FAST exam. Patients with multiple penetrating injuries who are hemodynamically normal can undergo computed tomography (CT) scan imaging of chest/abdomen/pelvis to more fully evaluate the location and trajectory of the fragments. CT scanning can be valuable in better characterizing the location of any projectiles and any associated injuries. In contrast, when a patient presents in shock with multiple penetrating injuries of the abdomen and thorax, a rapid sequence of diagnostic procedures, including chest x-ray (CXR) and FAST exam, is used to localize the sites of hemorrhage and determine which body cavity is addressed first. If profound shock is present and there is evidence of penetrating thoracic trauma, rapid placement of bilateral tube thoracostomies will allow assessment for pneumothorax and hemothorax.

Positive findings during these diagnostic procedures will guide decisions about initial operative therapy. Any evidence of penetrating cardiac injury with hemopericardium must be addressed first. If there is no associated massive hemothorax, median sternotomy provides optimal exposure to the heart and great vessels. If associated massive hemothorax is present, anterior thoracotomy with the patient "bumped" up on the side of injury is the preferred initial approach.

Indications for resuscitative thoracotomy are generally the same in combat as in civilian centers: patients in extremis with penetrating thoracic injury should rapidly undergo emergent left anterior thoracotomy for relief of tamponade by incising the pericardium anterior to the phrenic nerve. If there is no evidence of tamponade, other causes of exsanguinating hemorrhage should be evaluated. If the left pleural space is unrevealing, then extending the incision across the sternum to evaluate the right pleural space should be rapidly performed.

The recent Western Trauma Association algorithm has generated some controversy because it recommends very liberal thoracotomy indications compared with what has been historically advocated.⁴² However, in combat, because the patients are young and otherwise vital, such a liberal resuscitative thoracotomy approach is warranted and is espoused in the current version of the combat CPG on this topic.⁴³ To date, there are two reports on resuscitative thoracotomy in theater. Edens et al retrospectively found a 12% survival in a mixed population of U.S. and host nation casualties after resuscitative thoracotomy.⁴⁴ There were no survivors after blunt injuries (0/7). Of the survivors, 6 had primarily thoracic injuries and 6 had extrathoracic injuries (2 abdominal, 3 extremity, and 1 head/neck). Morrison et al reported 14 survivors of 65 patients (21.5%) who underwent resuscitative thoracotomy in a level III facility in Helmand Province, Afghanistan.⁴⁵ In this report, the time of loss of vitals correlated strongly with survivability. Of those who arrested prior to transport, 0 of 10 survived; of those who arrested in transport, 3 of 29 survived (10%); and of those who arrested in-hospital, 11 of 26 survived (42%).

An alternative resuscitative approach in patients with profound shock after trauma is balloon aortic occlusion, which is less invasive than resuscitative thoracotomy and in preclinical studies demonstrated improved outcomes.¹⁹

Early reports from two centers suggest that balloon aortic occlusion has merit in select patients although this would typically not include patients with penetrating thoracic injuries.²⁰ Another approach for patients in profound shock with extrathoracic injuries is to either apply a junctional tourniquet during resuscitation or to explore the injury directly to achieve proximal vascular control.^{46,47}

In the operating room, as the DCR continues, the surgeon must address the site of hemorrhage. Isolated injuries to the chest or abdomen are the exception rather than the rule in combat surgery, however. Just as in civilian trauma, thoracoabdominal wounds represent a significant challenge in the operating room because entering the wrong cavity at the outset greatly increases the patient's mortality.⁴⁸ Diagnostic adjuncts in the trauma bay or the operating room in such patients include tube thoracostomy and bedside ultrasound. In a patient in profound shock with multiple penetrating injuries, the focus should be placed on the cavity with obvious bleeding. If the FAST is positive for pericardial blood, a median sternotomy or bilateral anterior "clamshell" thoracotomy should be performed. The "clamshell" approach is often preferable in patients with multiple thoracic fragmentation wounds because it affords maximal exposure to both pleural spaces as well as the mediastinal structures (Fig. 61-7). In patients who respond initially to resuscitation, or in semi-stable patients with other potential causes for shock who require operative intervention, subxiphoid pericardial window remains a useful diagnostic adjunct. In patients with an indication for laparotomy and penetrating thoracic injuries, we advocate insertion of unilateral or bilateral tube thoracostomies (depending on whether the thoracic injuries are unilateral or bilateral) as the laparotomy is being performed. If there is suspicion of cardiac injury in a patient undergoing laparotomy, a transabdominal pericardial window through the central tendon of diaphragm can be performed to assess for hemopericardium. The presence of pericardial blood

FIGURE 61-7 ■ Clamshell thoracotomy and laparotomy in a patient with penetrating thoracoabdominal injuries. This patient required repair of a ventricular laceration and colonic resection for a destructive transverse colon injury.

then warrants a sterno-laparotomy or a separate clam-shell thoracotomy if there is also significant hemorrhage from the chest tubes.

In damage control thoracic surgery, the principles of gaining hemostasis and controlling soilage apply just as they do in abdominal damage control.⁴⁹ (Management of specific thoracic injuries is addressed later in this chapter.) In patients with multiple injuries who have undergone DCR, a temporary closure should be performed for ready reexploration if hemorrhage occurs and for easy access to the body cavity of interest by others within the chain of evacuation. Prior to temporary closure, ongoing diffuse hemorrhage from raw surfaces should be treated with topical hemostatic agents such as spray thrombin either with or without Gelfoam, if available. Laparotomy pads or hemostatic dressings such as Combat Gauze (Z-Medica Corporation, Wallingford, CT) can also be applied to diffuse bleeding surfaces.⁵⁰

There are a number of approaches to temporary chest closure in such situations. One retrospective review demonstrated no deleterious outcomes from temporary chest closure with or without packing, although the closure techniques used were not well described in this report.⁵¹ In our opinion, tight packing must be avoided, because this will theoretically diminish venous return and hinder resuscitation efforts. Typically, if the lung is allowed to reexpand, the measures previously described will result in hemorrhage control when combined with aggressive repletion of coagulation factors. Our preferred approach is to fashion a “vac-pack” for the chest.⁴⁹ Thoracostomy tubes are inserted and positioned as if the chest will be closed definitively. A clear plastic sheet with fenestrations cut into it is then placed over the lung and the tubes and acts like the parietal pleura for the open chest cavity. Laparotomy pads, blue towels, or a vacuum sponge is then placed over the plastic sheet. If a negative pressure vacuum sponge is used, this is connected to the commercial vacuum canister and set at 75 mm Hg suction and the chest tubes placed to 20 cm H₂O suction. For the custom vac pack, another large chest tube or large-size channel drains are placed over the blue towel followed by more blue towels followed by a large Ioban (3M, Minneapolis, MN) adhesive dressing. The vac-pack drain is then connected to a Heimlich valve to prevent loss of negative pressure if suction is temporarily interrupted and then to wall suction at 75 mm Hg. This approach prevents lung herniation and tends to tamponade any chest wall bleeding, both of which can occur if skin-only (stapled) temporary closure is used.

ICU MANAGEMENT AND EVACUATION

In the ICU, patients with operative or nonoperative thoracic injuries should be closely monitored with continuous pulse oximetry, frequent vital signs, periodic laboratory tests (i.e., CBC, chemistries, ABG, lactate, PT/PTT), and either thromboelastography (TEG) or rotational elastometry (ROTEM). Lung-protective ventilator settings should be used for intubated patients (6–8 mL/kg predicted body weight). Crystalloid and colloid resuscitation should be minimized in favor of

blood product resuscitation until all coagulation parameters and TEG values are normalized and the base excess and lactate are either trending toward or within normal limits (>-6 and <2 mmol/L, respectively). Tube thoracostomies are generally kept on suction for at least the first 24 hours after placement, with CXR obtained after insertion and every morning thereafter. Swan-Ganz catheters are occasionally used for monitoring and guiding resuscitation in theater. However, with more recent evidence suggesting little benefit to this approach,^{52,53} Swan-Ganz catheters are generally reserved for older host-nation casualties with combined cardiac dysfunction and renal insufficiency.^{54,55}

Respiratory failure including mild, moderate, or severe acute respiratory distress syndrome (ARDS) can occur early in combat casualties who undergo massive resuscitation.^{56–58} In a retrospective analysis of the JTTR data, 6.4% of intubated casualties developed ARDS, which was independently associated with increased mortality.⁵⁸ Factors that increased the development of ARDS included large volumes of crystalloid and plasma. Thus, it is imperative that crystalloid use be minimized during hemostatic resuscitation and that plasma administration be curtailed once hemostasis has been achieved. A CPG for optimal management of patients who develop ARDS is currently under review. The principles of lung-protective ventilation and use of select adjunctive therapies still apply. However, in some cases, to safely evacuate these patients and make room for more casualties in the theater hospitals, ECMO-facilitated transport is both safe and prudent.^{27,37}

In level II facilities, plain films and ultrasound are used extensively, and follow-up CT imaging is used once the patient arrives at the level III facility. All level III facilities now have CT scan capabilities, which are used extensively to guide further interventions after the initial management. Images are available via network connection to minimize repeat imaging as much as possible. Such cross-sectional imaging is helpful in developing a management plan for patients who are hemodynamically stable but have multiple penetrating torso injuries.⁵⁹ Examples of diagnoses made with CT imaging (either alone or as a confirmatory study) during the authors' deployments and the indicated management are listed in [Table 61-3](#).

In recent years, the historic approach to hemostasis evaluation with TEG has been applied to trauma resuscitation.^{60,61} TEG measures the various phases of clot formation and remodeling with a wire filament immersed in a rotating cuvette, which contains a whole blood sample (with or without various reagents). Another similar series of assays, termed ROTEM, differs from TEG only in that rather than the cuvette spinning, the pin is immersed in the sample spins. The ROTEM system has a more rugged construction and seems to be more resistant to vibrational artifact, which makes it more appealing for use in an austere environment. Nonetheless, both TEG and ROTEM have been used to good effect in theater.^{62,63} The most attractive feature of using these assays is that the specific coagulopathic deficiency can be identified with more precision and thereby managed with targeted therapy. This includes not only factor deficiencies responsive to plasma infusion but

also defects in clot strength and even fibrinolysis managed with platelet infusion or antifibrinolytic therapy, respectively.

SPECIFIC THORACIC INJURIES

With regard to thoracic trauma, the establishment of the JTS and the research database, now called the Department of Defense Trauma Registry (DoDTR), has allowed a careful evaluation of both thoracic injuries and thoracic complications from trauma such as ARDS. Three reports on thoracic injuries have been published from the wars in Iraq and Afghanistan (Table 61-4). These include one

report exclusively on U.S. combat casualties⁶⁴ and two reports on all combat casualties with thoracic injuries.^{65,66} All of these retrospective reviews used the DoDTR and extracted injury information based on ICD-9 codes. Because the registry is continuously updated, the number of injuries identified and the overall incidence of thoracic trauma changed with time. However, it does appear that the thoracic trauma mortality rate has been overall higher in this conflict than in prior wars. The most likely explanation for this observation is that more critically injured patients are arriving at medical facilities with detectable vitals regardless of their salvageability. Thus, all of these patients, including those with nonsurvivable injuries, are listed in this mortality rate. A more useful number, which captures the entire system of care and also reflects the quality of preventive measures such as ballistic armor, is the case fatality rate, which is simply all deaths divided by all injuries regardless of where the death occurs—such an analysis for patients with thoracic trauma has yet to be done for the most recent conflicts.

The prevalence of IEDs in recent conflicts has led to patients frequently presenting with multiple fragmentation injuries. These IEDs often contain ball bearings, bolts, or other scrap metal pieces intended to be projectiles. In addition, by obscuring the device as a roadside bomb buried under soil and rocks, the dirt and rocks become projectiles, leading to massively contaminated wounds involving multiple body cavities. Another common design for IEDs is large caliber munitions strung together. These munitions often produce large fragments of the shell casing, which can cause large wounds (see Fig. 61-2).

When assessing patients with multiple penetrating injuries, standard advanced trauma life support (ATLS) algorithms are followed to guide initial resuscitation. Patients with injuries involving both the thorax and abdomen add an additional layer of complexity to the initial evaluation. Similarly, multiple traumatic extremity amputations from a blast event can add even more confusion because there may or may not be additional occult sites of hemorrhage. All of these different types of patients challenge the most experienced surgeon, and mistakes in management can have dire consequences.

Almost all of these patients with large, complex open wounds will require surgical intervention for wound débridement at a minimum. If the patient is stable at presentation, CT imaging is useful in identifying smaller fragment injuries that have violated the thoracic cavity. If the patient is unstable at presentation, CT imaging after initial stabilization can also be helpful given the number

TABLE 61-3 Diagnoses Made with CT either as a Stand-alone Study or as a Confirmatory Test

Injury	Management
Occult pneumothorax	Follow-up CXR prior to aeromedical evacuation
Enlarging pneumothorax	Tube thoracostomy
Retained hemothorax	Tube thoracostomy, VATS, or thoracotomy
Pulmonary laceration	ICU monitoring
Cervical tracheal transection	Primary repair, tracheostomy below injury
Empyema, bronchopleural fistula	Thoracotomy, decortication, intercostal muscle flap
Pericardial effusion	Cardiac repair
Intracardiac fragment	Cardiac repair, removal of projectile
Blunt traumatic descending thoracic aortic injury	Thoracotomy, primary aortic repair
Left subclavian artery/vein transection	Sternotomy, trap door extension, direct suture repair
Superior vena cava/right atrial junction injury	Sternotomy, primary repair
Evolving tension bilothorax	Thoracotomy, bile/blood evacuation and laparotomy with diaphragm repair, posterior hepatorrhaphy, and anterior closed suction drainage
Ascending aortic dissection (nontraumatic)	Blood pressure control, CCATT transport, definitive repair in Germany

CCATT, Critical Care Air Transport Team; CT, computed tomography; CXR, chest x-ray; ICU, intensive care unit; VATS, video-assisted thoracic surgery.

TABLE 61-4 Retrospective Reviews on Combat Thoracic Injuries from Iraq and Afghanistan

Study	Population	Years	N	Incidence	Mortality	Notes
Propper et al ⁶⁵	All casualties	2002-2008	1660	4.9%	12%	U.S. troops = 565; coalition troops = 261; civilians = 819
Ivey et al ⁶⁴	U.S. only	2003-2011	2049	8.6%	8.3%	Battle injuries = 1713; nonbattle injuries = 336
Keneally and Szpisjak ⁶⁶	All casualties	2002-2012	7570	10%	10.5%	Pulmonary laceration and thoracic vascular injury increase mortality

of small fragments and possible occult injury. Simple pneumothorax or hemothorax is managed with tube thoracostomy with typical indications for proceeding to thoracotomy. All open wounds require aggressive soft tissue débridement to prevent sepsis, as described in one of the most important combat CPGs.⁶⁷ These wounds are often heavily soiled and require multiple repeat débridements. The combination of single-lung ventilation and video thoracoscopy is available at level III MTFs in-theater and is used selectively for foreign body removal based on size, degree of contamination, and location (Fig. 61-8). Fragments located in mediastinum or pericardial space should be surgically evaluated in most cases because of the risk of occult injury to nearby structures (Fig. 61-9). The surgical approach can be full or partial sternotomy, thoracotomy, or video thoracoscopy based on location and suspicion for visceral injury.

Large chest wall defects lead to open pneumothorax and respiratory failure (see Fig. 61-2 and Video 61-1). Endotracheal intubation with positive pressure

ventilation followed by operative repair can be lifesaving. Our review of patients with thoracic injury⁵⁷ identified 264 patients with open chest wound and another 26 with flail chest. These patients should be considered to have underlying pulmonary contusion and lung-protective ventilation, and judicious administration of crystalloid and plasma volume can minimize progression of acute lung injury and development of ARDS. Exposure of intrathoracic organs may be adequate using the original soft tissue defect, but the addition of a standard posterolateral thoracotomy can improve exposure. Sparing of the latissimus dorsi muscle for potential rotational flap closure is an important consideration during the initial surgery; however, control of hemorrhage and repair of bronchial tree injuries must take priority over future reconstruction. At the initial surgery, once hemostasis is obtained, ongoing significant air leak should be addressed and gross contamination and devitalized tissues débrided. For definitive closure, several large-bore thoracostomy tubes should be placed, ribs should be approximated with either heavy monofilament sutures or wire, and chest wall musculature closed if possible. Superficial layers of the chest wall should remain open and negative pressure wound therapy should be used. If there is a soft tissue defect that does not allow adequate closure of the chest wall, a temporary closure using either negative pressure wound therapy dressing or modified “vac-pack” (as previously described) can be used. Pain control and adequate pulmonary toilet after such injuries can be difficult and may require that the patient remain intubated and sedated.

Among patients presenting with thoracic injuries in the conflicts in Iraq and Afghanistan,⁵⁷⁻⁵⁹ injuries to the heart (3.8%), esophagus (1.5%), bronchus (0.6%), aorta (0.6%), or vena cava (0.6%) are rare, and even lung laceration (9.3%) and other major vessel injury (9.6%) are uncommon. The reasons behind this are twofold: (1) relative protection due to location and use of body armor and (2) lethality of injuries to these structures. Despite their rarity, rapid diagnosis and appropriate intervention can produce good outcomes.

For thoracic aortic or arch vessel injuries, direct suture repair (Fig. 61-10) or interposition grafting is often required. For extremity vascular injuries, use of a temporary shunt has been shown to successfully restore distal flow while then permitting a thorough reassessment of other injuries in the setting.^{68,69} A similar approach can be applied to injuries of the aortic arch branches but should be used only in extreme circumstances.

Hemorrhage from peripheral pulmonary parenchymal injuries can be managed with tractotomy and suture repair of bleeding pulmonary lacerations or with nonanatomic pulmonary resection. Massive bleeding from the pulmonary hilum can be temporarily controlled by dividing the inferior pulmonary ligament and 180-degree rotation of the lung. This maneuver will occlude the pulmonary vasculature and stop the hemorrhage. If necessary, placement of a hilar clamp can be used to gain hemostasis (Fig. 61-11), although this will likely commit the patient to a pneumonectomy. Pneumonectomy for traumatic injuries carries a high mortality (>50%), frequently is associated with acute pulmonary

FIGURE 61-8 ■ **A**, Thoracoscopic view of an intrathoracic bolt from a blast event. **B**, The bolt was successfully retrieved, and the patient recovered uneventfully. (Courtesy Lt. Col. Rachel Hight, MD.)

FIGURE 61-9 ■ **A**, A patient with multiple fragmentation injuries underwent a complete trauma evaluation and was found to have a ball bearing in the region of the right heart (*arrow*). Pericardial FAST was negative for fluid and he had indications for a trauma laparotomy. **B**, Postoperatively, the patient underwent a follow-up chest x-ray, which demonstrated that the ball bearing had migrated (*arrow*). A follow-up computed tomography scan demonstrated that the fragment was likely in the pericardium. Consequently, the patient underwent exploration through a median sternotomy and was found to have a small laceration of the right ventricle, which was repaired primarily. FAST, Focused assessment with sonography for trauma.

hypertension and right ventricular failure, and may necessitate institution of ECMO to achieve survival.

Cardiac lacerations must typically be repaired directly during damage control surgery to eliminate ongoing bleeding and cardiac tamponade. Most cardiac injuries that arrive at level II or III MTFs can frequently be repaired with polypropylene sutures placed in a horizontal mattress fashion using polytetrafluoroethylene (PTFE) felt or autologous pericardial pledgets. In the deployed setting, cardiopulmonary bypass capability does not exist; so intracardiac repair for septal defects or valvular dysfunction is not feasible. Some techniques, mostly of historical interest only, used in civilian trauma centers are worth mentioning as an adjunct for repair of more extensive myocardial injuries.

Induction of ventricular fibrillation using epicardial electrodes with alternating current (AC) device was commonly used in the early years of cardiac surgery and is still occasionally used by some surgeons. This technique will reliably stop a vigorously beating tachycardic heart and allow the rapid placement of several repair sutures in the ascending aorta, aortic arch vessels, or ventricular myocardium. When followed by defibrillation with standard internal paddles within 2 or 3 minutes, cardiac function can typically be readily resumed. If necessary, internal cardiac massage can be performed to assist with defibrillation because the distended fibrillating heart can be resistant to defibrillation. Typically 20 Joules is used for defibrillation with internal paddles, but increasing energy levels up to 40 Joules is acceptable. Alternatively, if a large laceration of one of the atria is present and not easily controlled by application of partial occlusion clamp or

simple suture ligation, in-flow occlusion will rapidly empty out the heart and allow improved visualization. This is performed by snaring or clamping both the superior and the inferior vena cava at their junction to the right atrium and thereby preventing filling of the right-sided cardiac chambers. The surgeon must be prepared to deal with ventricular fibrillation with this approach as well; prolonged inflow occlusion will lead to decreased coronary perfusion and fibrillation.

Exposure and repair of descending thoracic aorta or the major arch vessels within the mediastinum or left pleural space can be challenging. The surrounding hematoma can make obtaining proximal and distal control difficult, and once the injury is decompressed, the patient will rapidly exsanguinate without vascular control. Precise identification of site of bleeding from vena cava or other large veins is often difficult. In select situations in combat hospitals, endovascular therapy has been used. Several techniques may be used with open surgical repair of these injuries. Simple digital compression at the site of vascular injury should be used as initial control, if possible. This will usually control most bleeding and maintains distal perfusion while a more carefully planned approach is developed. Once digital control of the bleeding is obtained, the anesthesiologist can “catch up” on resuscitation without excessive administration of crystalloid. For small injuries, digital compression can be converted to compression by an assistant with a sponge stick or Kittner while suture repair with 3-0 or 4-0 polypropylene on an appropriately large needle is performed. If a more extensive injury is present, placement of vascular clamps around the injury may be required. Primary suture repair,

FIGURE 61-10 ■ **A**, Blunt aortic injury with a pseudoaneurysm seen on computed tomography scan. **B**, The injury was repaired primarily using a clamp and sew technique through a left thoracotomy. *PA*, Pulmonary artery.

patch angioplasty, or interposition grafting with appropriate size Dacron or ePTFE conduit is then performed. Saphenous vein is not large enough to use as conduit for such large caliber vessels, and use of prosthetic graft material is justified if primary repair cannot be performed. Large veins can undergo venorrhaphy for hemorrhage control even if the lumen is somewhat compromised. Ligation for control of hemorrhage is occasionally required. Interposition grafting of large veins with prosthetic material is typically not recommended because of poor patency and risk of thrombosis and pulmonary embolism.

Esophageal injuries are unusual in penetrating trauma, and their management in the combat environment is similar to that in civilian practice. Management is determined by the site of primary injury, associated injuries, condition of the patient, degree of local suppuration, condition of the esophageal tissues, and delay since injury.

FIGURE 61-11 ■ A hilar clamp was applied emergently in this combat casualty to achieve hemostasis following a transmediastinal gunshot wound. The patient was returned to the ICU for resuscitation. A pneumonectomy was required upon return to the operating room. (Courtesy American College of Surgeons.)

Primary repair using a two-layer closure with tissue buttressing (such as intercostal muscle flap) and adequate drainage is the preferred method. Establishment of reliable enteral feeding access in the setting of an esophageal injury is an important adjunct that makes dealing with any esophageal leak much easier to manage. In the markedly unstable patient or when faced with a delayed diagnosis with extensive contamination, placement of T tube, adequate drainage tubes, and proximal/distal decompression can be a temporizing option. Esophageal replacement is rarely required and should not be considered a good option in the multiply injured patient.

LONG-TERM OUTCOMES

In previous wars, destructive thoracic injuries and limited experience with soft tissue coverage techniques resulted in significant chest wall deformities (Fig. 61-12). In our most recent experience, however, patients with combat thoracic injuries generally have an excellent functional recovery. This has included patients with bronchial stump leaks and those initially managed with ECMO following trauma pneumonectomy. Formal testing of pulmonary function in these patients is sometimes limited by long-term rehabilitation from extremity trauma,

FIGURE 61-12 ■ Posttraumatic empyema was managed with open drainage and thoracoplasty during World War I. This resulted in significant chest wall deformities that were quite disabling. Modern thoracic surgical techniques result in much more functional outcomes. (From Brewer LA: The contributions of the Second Auxiliary Surgical Group to military surgery during World War II with special reference to thoracic surgery. *Ann Surg* 197[3]:318–326, 1983, Figure 7, with permission.)

but this has prompted new interest in defining alternative testing standards comparable to established functional studies such as the 6-minute walk test. To date, there has not been a formal longitudinal study of survivors with thoracic injuries from the recent conflicts; however, plans to undertake this important study are currently in development.

SUMMARY

Significant advances in our system of care for multiply injured patients have improved outcomes for severely injured patients. In those with thoracic injuries, the mortality remains relatively high; this should prompt us to continue to push for improved identification and management of these challenging injuries. Going forward, we need to continue to glean lessons from both our combat experience and from our experiences in high-volume civilian trauma centers so that in future conflicts, our outcomes will be even better than they are today. In the combat theater, cardiothoracic surgeons, trauma surgeons, and many other subspecialists have a part in the care of these patients—a paradigm that will likely continue into the future with our all-volunteer military medical corps. Thus, we need to continue to prepare all of these medical professionals to manage patients with challenging combat wounds, including complex thoracic injuries, to ensure we provide the best possible support for those individuals who are risking their lives in defense of our freedom.

CHAPTER OUTLINE

ASSESSMENT

POPULATIONS AT RISK

MECHANISMS OF INJURY

STRATEGIES FOR REDUCING INJURY

NEUROPROTECTIVE STRATEGIES

PROGNOSIS

The brain is the effector organ for all behavior, innate and learned. It is the monarch of blood flow and will shut down all other vascular systems to preserve its own supply. Conversely, dysfunction in other organs can adversely affect brain function. It monitors other organ systems and is acutely sensitive and responsive to both the external and internal environment. Thus, even small injuries to the brain may produce symptomatic, functional losses that would not be detectable or important in other organs. Regional hypoperfusion, edema, microemboli, circulating cytotoxins, or subtle changes in blood glucose, insulin, or calcium may result in changes in cognitive function, ranging from subtle to profound. A small 2-mm infarct may cause a disruption of behavioral patterns. Physiologic and physical function changes can pass unnoticed, be accepted and dismissed, or profoundly compromise the patient's quality of life. Move the lesion half a centimeter, and the same volume lesion may result in a catastrophic stroke. Thus the brain is the most sensitive organ exposed to damage by cardiopulmonary bypass (CPB) and cardiac surgery and also the organ that, with the heart, is most important to protect.

ASSESSMENT

Routine assessment of neurologic injury, which occurs in the setting of cardiac surgery, is not done for most patients because of the priority of the cardiac lesion and because of costs in time and money. General neurologic examinations by members of the surgical team or individuals lacking specialized training are not adequate to rule out subtle neurologic injuries, and this is the principal reason that the incidence of stroke, neurologic, or neuropsychologic injury varies widely in the surgical literature.¹⁻³

For studies designed to assess or reduce neurologic injury in the setting of cardiac surgery, nonroutine preoperative and postoperative tests are required. These special tests include a complete neurologic examination

by a neurologist or a well-trained surrogate. To improve accuracy, a single neurologist should conduct all serial examinations. A standardized protocol of examination should be followed, with uniform reporting of results. The basic, structured examination includes a mental state examination; cranial nerve, motor, sensory, and cerebellar examinations; and examination of gait, station, deep tendon, and primitive reflexes.

The most obvious neurologic abnormalities are paresis; loss of vital brain functions such as speech, vision, and comprehension; and coma. These are commonly lumped under the general heading of stroke. Disorders of awareness or consciousness can include coma, delirium, and confusion, but transitory episodes of delirium and confusion are often dismissed as being caused by anesthesia or medications. More subtle losses are determined by comparison of preoperative and postoperative performances using a standard battery of neuropsychologic tests prepared by a group of neuropsychologists.⁴ A neuropsychologic examination is basically an extension of the neurologic examination with a much greater emphasis on higher cortical function. Dysfunction is objectively defined as a deviation from the expected, relative to a large population. For example, although performing at a 95 IQ level is in the normal range, it is low for a physician, and a search for a neurologic impairment would be triggered by such a poor performance. A 20% decline in two or more of these tests, compared to the patient's own baseline, suggests a neuropsychologic deficit that should be followed until resolved or not resolved.⁵ In studies involving long-term follow-up, the inclusion of a control group of unoperated patients with the same disease and of similar demographics helps define the causes of neuropsychologic decline that occurs later than 3 to 6 months after surgery.⁶

Computed axial tomograms or magnetic resonance imaging (MRI) scans are essential for the definitive diagnosis of stroke, delirium, or coma. Preoperative imaging is usually not necessary when new techniques such as

FIGURE 62-1 ■ Preoperative brain MRI from patient undergoing extensive cardiac surgery superimposed on identical images taken at 3 months and 1 year after surgery. The appearance of the ventricles at 1 year indicates brain shrinkage, presumably from apoptosis of neurons.

diffusion-weighted MRI imaging, MRI spectroscopy, or MRI angiography are used to assess possible new lesions after surgery.⁷⁻⁹ However, recent studies demonstrate patients with dementia have a loss in cell volume as a result of micro-infarctions that are not detectable with current radiologic techniques.¹⁰ Histologic studies performed on patients who did not survive cardiac surgery have demonstrated millions of small lipid microemboli, which may result in massive cell loss and increased volume of ventricles (Fig. 62-1).

Biochemical markers of neurologic injury after cardiac surgery are relatively nonspecific and inconclusive. Neuron-specific enolase (NSE) is an intracellular enzyme found in neurons, normal neuroendocrine cells, platelets, and erythrocytes.¹¹ S-100 is an acidic calcium-binding protein found in the brain.^{12,13} The beta dimer resides in glial and Schwann cells. Both S-100 and NSE increase in spinal fluid with neuronal death^{12,13} and may correlate with stroke or spinal cord injury after CPB.¹⁴ However, plasma levels are contaminated by aspiration of wound blood into the pump and hemolysis and are often elevated following prolonged CPB in patients without otherwise detectable neurologic injury.¹⁵ Newer bloodborne biochemical markers are being identified but, as of yet, have not been shown to be diagnostic for subtle neurologic injury.

POPULATIONS AT RISK

Advancing age increases the risk of stroke or cognitive impairment in the general population, and surgery, regardless of type, increases the risk still higher.¹⁶ In 1999 Hogue and colleagues reported the risk of stroke during coronary artery bypass graft (CABG) surgery to be directly related to age and other factors.¹⁷ A European study compared 321 older adult patients without surgery to 1218 patients who had noncardiac surgery and found a 26% incidence of cognitive dysfunction 1 week after operation and a 10% incidence at 3 months.¹⁸ Between 1974 and 1990 the number of patients undergoing cardiac surgery who were older than 60 years and older than 70 years increased twofold and sevenfold, respectively.¹⁹

Today patients 75 years of age and older commonly receive cardiac surgery.²⁰ Genetic factors also influence the incidence of cognitive dysfunction following cardiac surgery.²¹ The incidence of cognitive dysfunction at 1 week following cardiac surgery is approximately double that of noncardiac surgery.

As the age of patients undergoing cardiac surgery increases, the number of patients with multiple risk factors for neurologic injury also increases. Risk factors for adverse cerebral outcomes are listed in Table 62-1.²² These factors are divided into stroke with a permanent fixed neurologic deficit (type 1) and coma or delirium (type 2). Hypertension and diabetes occur in approximately 55% and 25% of cardiac surgical patients, respectively.²³ Fifteen percent have carotid stenosis of 50% or greater, and up to 13% have had a transient ischemic attack or prior stroke. The total number of MRI atherosclerotic lesions in the brachiocephalic vessels adds to the risk of stroke or cognitive dysfunction,²⁴ as does the severity of atherosclerosis in the ascending aorta as detected by epiaortic ultrasound scanning.²⁵ Palpable ascending aortic atherosclerotic plaques markedly increase the risk of right carotid arterial emboli as detected by Doppler ultrasound.²⁶ The incidence of severe aortic atherosclerosis is 1% in cardiac surgical patients younger than 50 years and is 10% in those aged 75 to 80 years.²⁷

MECHANISMS OF INJURY

The three major causes of neurologic dysfunction and injury during cardiac surgery are microemboli, hypoperfusion, and a generalized inflammatory reaction, all three of which can occur in the same patient at the same time for different reasons. Most intraoperative strokes are caused by the embolization of atherosclerotic material from the aorta and brachiocephalic vessels. This occurs as a result of manipulation of the heart and major thoracic vasculature as well as dislodgement of atheromata from shearing forces directed at the walls of vessels from inflow CPB cannulae.²⁸ Microemboli are distributed in proportion to blood flow²⁹; thus, reduced cerebral blood flow reduces microembolic injury but increases the risk of

TABLE 62-1 **Adjusted Odds Ratios for Type I and Type II Cerebral Outcomes Associated with Selected Risk Factors**

Factor	Model for Type I Cerebral Outcome	Model for Type II Cerebral Outcome
Significant Factors, <i>P</i> < 0.05		
Proximal aortic atherosclerosis	4.52	
History of neurologic disease	3.19	
Use of intra-aortic balloon pump	2.60	
Diabetes mellitus	2.59	
History of hypertension	2.31	
History of pulmonary disease	2.09	2.37
History of unstable angina	1.83	
Age (per additional decade)	1.75	2.20
Systolic blood pressure > 180 mm Hg at admission		3.47
History of excessive alcohol consumption		2.64
History of CABG		2.18
Dysrhythmia on day of surgery		1.97
Antihypertensive therapy		1.78
Other Factors (<i>P</i> not significant)		
Perioperative hypotension	1.92	1.88
Ventricular venting	1.83	
Congestive heart failure on day of surgery		2.46
History of peripheral vascular disease		1.64

CABG, Coronary artery bypass graft.

FIGURE 62-2 ■ High-magnification photomicrograph showing small capillary arteriolar dilations (SCADs) from the brain of a patient dying soon after cardiac surgery. **A** and **B**, SCADs in arterioles (dark arrows), vasospasm. (Alkaline phosphatase–stained, celloidin-embedded, $\times 50$.) **C**, SCADs stained black with osmium, indicating fat. Arrows indicate tissue edema and vacuoles from injury. (Osmium-stained, paraffin-embedded, 5- μ m-thick section.)

hypoperfusion.³⁰ During CPB both alpha-stat acid-base management and phenylephrine reduce cerebral injury in adults, probably by causing cerebral vessel vasoconstriction and reducing the number of microemboli.^{31,32} Air,³³ atherosclerotic debris,³⁴ and fat are the major types of microemboli causing brain injury in clinical practice, and all cause neuronal necrosis by blocking cerebral vessels.³³ Massive air embolism causes a large ischemic injury, but gaseous cerebral microemboli may directly damage

endothelium in addition to blocking blood flow.³⁴ The recent identification of unique small capillary arteriolar dilations (SCADs) in the brain associated with fat emboli (Fig. 62-2)³⁵ raises the possibility that these emboli not only block small vessels but also release cytotoxic free radicals, which may significantly increase the damage to lipid-rich neurons.

Anemia and elevated cerebral temperature increase cerebral blood flow but may cause inadequate oxygen

delivery to the brain³⁶; however, these conditions are easily avoided during clinical cardiac surgery. Although some investigators speculate that normothermic and/or hyperthermic CPB surgery cause cerebral hypoperfusion,³⁷ experimental studies indicate that cerebral blood flow increases with temperature.³⁸ Brain injuries associated with this practice are more likely the result of increased cerebral microemboli, which produce larger lesions at higher cerebral temperatures.³⁹ Reduced brain temperature is protective against neural cell injury and remains an important neuroprotective strategy (Fig. 62-3).

All surgery, like accidental trauma, triggers an acute inflammatory response that can result in neurologic injury, but the continuous exposure of heparinized blood to nonendothelial cell surfaces followed by reinfusion of wound blood and recirculation within the body greatly magnifies this response in operations in which CPB is used. Although far from fully described and understood, this primary “blood injury” produces a unique response, which is different in detail from that caused by other threats to homeostasis.

The principal blood elements involved in this acute defense reaction are contact and complement plasma protein systems, neutrophils, monocytes, endothelial cells, and, to a lesser extent, platelets. When activated during CPB, the principal blood elements release vasoactive and cytotoxic substances, produce cell-signaling inflammatory and inhibitory cytokines, express complementary cellular receptors that interact with specific cell-signaling substances and other cells, and generate a host of vasoactive and cytotoxic substances that circulate.⁴⁰ Normally these reactive blood elements mediate and regulate the defense reaction,⁴¹⁻⁴³ but during CPB an orderly, targeted response is overwhelmed by the massive activation and circulation of these reactive blood elements. This massive attack damages the endothelium, increases the size of ischemic lesions, and causes organ dysfunction. The parenchyma of the brain is shielded from this attack by the blood-brain barrier. However, embolization and cytotoxic substances damage the barrier and cause neuronal injury and necrosis. This liberates

S-100, NSE, and other neuronal proteins into the spinal fluid and produces cerebral edema.⁴⁴

STRATEGIES FOR REDUCING INJURY

Important methods for reducing emboli deserve emphasis. Principles include adequate anticoagulation, the washing of blood aspirated from the surgical wound, the filtering of arterial inflow and venous outflow, strict control of all air entry sites within the perfusion circuit, removal of residual air from the heart and great vessels, and avoidance of atherosclerotic emboli.^{45,46}

Many intraoperative strategies are available to reduce cerebral atherosclerotic embolization. These include routine direct contact epiaortic echocardiography of the ascending aorta to detect both anterior and posterior atherosclerotic plaques and to find sites free of atherosclerosis for placing the aortic cannula and grafts.⁴⁷ Special catheters with or without baffles or screens have been developed to reduce the number of atherosclerotic emboli that reach the cerebral circulation.⁴⁸ In patients with moderate or severe ascending aortic atherosclerosis, a single application of the aortic clamp as opposed to partial or multiple applications is strongly recommended and has been shown to reduce postoperative neurocognitive deficits in a large clinical series.⁴⁹ Retrograde cardioplegia is preferred over antegrade cardioplegia in these patients to avoid repeated aortic injections of cardioplegic solution.⁵⁰ No aortic clamp may be safe or even possible in some patients with severe atherosclerosis or porcelain aorta. If intracardiac surgery is required in these patients, deep hypothermia may be used with or without graft replacement of the ascending aorta. If only revascularization is needed, pedicled single or sequential arterial grafts,⁵¹ T- or Y-grafts from a pedicled mammary artery,⁵² or vein grafts anastomosed to arch vessels can be used. Patients with intracardiac thrombus or vegetations require aortic cross clamping before cardiac manipulation to avoid dislodging embolic material. In open cardiac surgery, the removal of air from cardiac chambers is important to avoid embolization. Flooding the field with

FIGURE 62-3 ■ Experimental brain ischemia from glass bead embolization. **A**, Large area of ischemia in an animal at normothermia. **B**, From an animal embolized at 32°C with no evident ischemia. Paraffin-embedded, stained for heat shock protein.

carbon dioxide is one answer to the problem but is cumbersome and potentially dangerous to the surgical team.⁵³ The advent of routine transesophageal echocardiography to detect and aid in air removal has made this adjunct less important.⁵⁴

In-depth or screen filters are essential for cardiectomy reservoirs, although washing cardiectomy blood is important because fat emboli are not effectively filtered. The efficacy of arterial line filters is controversial; screen filters with a pore size less than 20 μm cannot be used because of flow resistance across the filter.⁵⁵ However, air and fat emboli can pass through filters, although 20- μm screen filters more effectively trap microemboli than do larger sizes.⁵⁶ The Northern New England Cardiovascular Disease Study Group has published innovative techniques using small-pore venous reservoir and arterial line filters to eliminate microemboli generated in CPB circuits.⁵⁷

NEUROPROTECTIVE STRATEGIES

Recommended conditions for protecting the brain during CPB include mild hypothermia (32°C to 34°C) (see Fig. 62-3) and hematocrit above 25%.³⁸ Temporary increases in cerebral venous pressure caused by superior vena cava obstruction and excessive rewarming above blood temperatures of 37°C should be avoided.^{39,58} A randomized study in which patients were mildly rewarmed to 35°C core temperature demonstrated improved neurocognitive outcomes over patients rewarmed to 37°C.⁵⁹ Either jugular venous bulb oxygen saturation or near-infrared cerebral oximetry is recommended for monitoring cerebral perfusion in patients who may be at high risk for cerebral injury.⁶⁰ A randomized study demonstrated improved overall outcomes using near-infrared spectroscopy but no significant improvement in stroke incidence.⁶¹ This may indicate that maintenance of adequate cerebral oxygenation is a surrogate for overall adequate perfusion during bypass but has little effect on microembolic brain damage.

Barbiturates reduce cerebral metabolism by decreasing spontaneous synaptic activity⁶² and provide a definite neuroprotective effect during clinical cardiac surgery using CPB.⁶³ Unfortunately these agents delay emergence from anesthesia and prolong intensive care unit stays. One study of high-risk patients randomized to aprotinin or placebo found a powerful protective effect against stroke for full-dose aprotinin in CABG patients.⁶⁴ However, renal and cardiac toxic side effects limit effectiveness. NMDA (*N*-methyl-D-aspartate) antagonists, which are effective in animals, provide mild protection compared to control patients, but have a high incidence of neurologic side effects.⁶⁵ A small study demonstrated a neuroprotective effect of lidocaine, but this beneficial effect has not been reproduced.⁶⁶ Currently no pharmacologic agent is recommended for protection of the central nervous system during CPB.

Off-pump myocardial revascularization theoretically avoids many of the causes of cerebral injury resulting from CPB, but, as noted earlier, many causes of neuronal injury are independent of CPB and related to

atherosclerosis and air entry sites into the circulation. Many surgeons believe that off-pump coronary artery bypass (OPCAB) surgery is safer than on-pump operations, but studies testing this hypothesis have yielded inconsistent results in measured neurologic outcomes. Nonrandomized measurements of carotid emboli by Doppler ultrasound indicate fewer emboli and slightly improved neurocognitive outcomes in high-risk patients who have off-pump surgery.⁶⁷ Two smaller studies suggest that high-risk patients benefit disproportionately from off-pump coronary surgery.^{68,69} The only large trial that demonstrated superior results from OPCAB was a meta-analysis of 120,000 propensity-matched patients that demonstrated highly statistically significant benefits in mortality and stroke.⁷⁰ One year later, a large database review found no advantage in any outcome measures for off-pump surgery.⁷¹ Until the results of a large prospective randomized trial are published, no firm conclusions can be made regarding neuroprotection.

PROGNOSIS

Patients with intraoperative stroke or who develop stroke symptoms in the first week after surgery often improve in direct relation to the lesion size and location on imaging studies. Neuropsychologic deficits that are present after 3 months are almost always permanent.⁷² Assessments after that time are confounded by development of new deficits, particularly in older adult patients.^{10,73}

The difficulty of separating intraoperative brain injury from that which occurs in the early or late postoperative period has been addressed by a reanalysis of data published earlier. The authors tracked specific neuropsychologic deficits that persisted unchanged for 6 months (persistent deficits) and separated them from new deficits that appeared after surgery⁷⁴ (Fig. 62-4). Using this

FIGURE 62-4 ■ Bar graph with results of neuropsychologic testing at 6 months after coronary artery bypass graft (CABG) surgery performed using three different techniques. Note patients with single aortic clamping have many fewer persistent neuropsychologic deficits than patients operated with multiple aortic clamping or off-pump coronary artery bypass (OPCAB).

technique it is possible to accurately measure surgical brain injury and design techniques to eliminate this important cause of morbidity. Late follow-up studies should include a control group with similar risk factors but not having cardiac operations.⁷⁵ This technique demonstrated similar outcomes in surgical and nonsurgical controls at 3 years, putting to rest the previous fear that surgical patients had recurrent neurocognitive deficits and were thus at greater risk for poor long-term outcomes. In a recent study, a group of surgical patients who were evaluated with preoperative and postoperative neuropsychologic studies had rigid control of postoperative cardiovascular risk factors.⁷⁶ They demonstrated no delayed or late cognitive decline. This result offers hope that aggressive medical therapy can complement skillful surgery in preventing neurologic injury.

THE FUTURE OF CARDIOPULMONARY BYPASS

INTRODUCTION AND HISTORY

Cardiopulmonary bypass (CPB) is one of the most important biomedical inventions in the history of health care, rivaling the development of roentgenography and hemodialysis in its clinical impact. The scope of its application is far reaching. Its birth paralleled the evolution of an entire surgical subspecialty, and without its use, surgeons would be intimidated by the prospect of intracardiac repair.

Despite the belief that the need for CPB would be significantly diminished because of the surge in interest in off-pump coronary artery bypass grafting (CABG), the predictions have not materialized. Off-pump trends peaked at 24% in 2003, steadily declining thereafter to a stabilized percentage of 19% in 2011.¹ In many practices,

complex multiple arterial reconstruction and minimal-access surgery such as mini-thoracotomy mitral valve surgery are more comfortably and accurately approached using longer periods of CPB and optimized myocardial protection. Therefore, every surgeon must have a comprehensive understanding of all aspects of CPB, from the physiology of gas exchange to the molecular mechanisms characteristic of biocompatibility.

The evolution of CPB reflects ingenuity bred of necessity. A parallel discovery that contributed to the feasibility of extracorporeal circulation was the isolation of the natural anticoagulant heparin. Dr. John H. Gibbon, Jr. (Fig. 63-1), a “receptive and talented surgeon with foresight ... who could envision an intact surviving patient beyond the isolated organ studies,”² was the inventor of the Gibbons-IBM oxygenator. In 1953, this device was successfully used to correct an atrial septal defect. Although

FIGURE 63-1 ■ Dr. John H. Gibbon, Jr. (1903-1973).

it was initially successful, three subsequent attempts at intracardiac repair were fatal, resulting in a self-imposed moratorium on its clinical use. Nevertheless, the feasibility of this approach had been demonstrated.

The first clinically successful film and bubble oxygenators brought blood in direct contact with respiratory gases to equilibrate with them. Complications related to blood trauma eventually led to a decline in their popularity, and they are rarely used today. Membrane oxygenators were introduced in the 1950s after the observation by Kolff and Berk³ that venous blood was oxygenated while flowing through a cellophane dialysis tube in contact with O₂-containing dialysate. The first membranes were relatively impermeable to gases, requiring huge surface areas and massive priming volumes. Formed of silicone rubber, they were designed in either an extraluminal format (blood flowing on the outside of the tube with gas on the inside) or, less often, in an intraluminal format (the reverse). The next generation of oxygenators were prepared with silicone-coated polypropylene, whereas currently many commercial oxygenators use polymethylpentene fibers. Other refinements have been subtle but significant, and we now have oxygenators with surface areas of over 2.0 m² configured with minimal blood volume. The resulting minimization of prime volume has contributed more than any other factor to blood conservation practice in modern-day cardiac surgery.

TECHNICAL ASPECTS

Device Overview

Inflow and outflow cannulas from the patient are attached to the oxygenator device with tubing composed of poly-

vinylchloride, polyurethane, or silicon rubber. Blood enters the venous reservoir from the venous circulation. Through separate inflows on the reservoir, blood can also be returned from the pericardial well (cardiotomy blood) and from cardiac and aortic vents. A pump is used to divert the venous reservoir blood to the oxygenator. After the blood passes through the integrated heat exchanger and oxygenator, it is circulated through an arterial filter and bubble trap and returned to the patient through the arterial cannula (Fig. 63-2). Cardioplegia setups are often intimately incorporated into the CPB circuit.

Principles of Current Oxygenator Design and Function

Diffusion of gases at the blood-membrane interface can be predicted by Fick's law, which states that the rate of diffusion is proportional to the partial pressure gradient of the gas in the direction of diffusion. The rate of gas transfer is also inversely proportional to the distance through which it must pass (the thickness of the membrane). The rate also depends on the property of *diffusivity* of the membrane biomaterial. Currently used membranes are permeable to O₂, but they are often less permeable to CO₂. The problem of poor diffusion of CO₂ was solved by the introduction of microporous membranes. These surfaces allow transient blood-gas interfacing at pore structures smaller than blood cells; however, the hydrophobic nature of the membrane results in changes in blood surface tension, blocking actual contact between the two phases. As a result, the interface in microporous membranes behaves like a very thin stagnant film of plasma water that offers little resistance to gas exchange. Progressive protein accretion at the pores occurs over time, resulting in a finite functional capacity, detected by worsening efficiency in gas transfer, which is why oxygenators must be replaced with long CPB runs (Fig. 63-3).

As opposed to the relatively facile transfer of O₂ gas through a membrane, when the O₂ is dissolved in plasma or blood, its diffusivity is 25 times less than that of CO₂. This difference is due to the more facile dissolution of CO₂ in plasma and due to the linear shape of the CO₂ dissociation curve as compared to the sigmoid shape of the O₂ dissociation curve. The patient's PaCO₂ can be decreased by increasing the rate of fresh gas flow, whereas alteration of the PaO₂ can be achieved only by enhancing the rate of blood flow exposure to the surface. This latter can be accomplished either by increasing the overall flow or by enhancing the efficiency of exposure. To achieve this, the path length (the distance the blood travels as it passes the gas-exchange surface) must be maximized. This modification is limited by the parallel need to increase the priming volume. Second, disturbed flow patterns can be used to promote mixing and to bring deoxygenated blood closer to the exchange surface. Mechanisms that interfere with the development of fully developed flow patterns enhance diffusion by keeping the boundary layer narrow. In an oxygenator, this can be accomplished by making the surface irregular or by positioning elements in the flow stream to disrupt smooth flow and to enhance mixing. This is the rationale for the extraluminal hollow fiber design.

FIGURE 63-4 ■ The effect of hypothermia on oxygen consumption (VO_2).

Hypothermia and Acid-Base Balance

The feasibility and applicability of hypothermia for heart surgery was first suggested by Bigelow and colleagues in 1950.⁴ They demonstrated the safety benefit of hypothermia as a means to decrease O_2 consumption during inflow occlusion in an animal model. O_2 consumption decreases by 50% for every $10^{\circ}C$ drop in temperature (Fig. 63-4). Lower flows decrease collateral flow and rewarming of the heart from contact with adjacent tissues, and they provide a margin of safety if equipment fails.

Hypothermia is associated with marked changes in blood pH and PCO_2 levels. With a rise in temperature,

CO_2 becomes less soluble in blood, and there is a greater tendency for the dissolved CO_2 to come out of solution (increased gaseous phase). Similarly, CO_2 solubility increases with decreasing temperature. When blood from a hypothermic patient (e.g., $24^{\circ}C$) is introduced into a CO_2 electrode for measurement, it is first warmed to $37^{\circ}C$ (increasing the amount of CO_2 in the gaseous phase), and therefore the measured partial pressure of CO_2 is higher than it was in reality at the cooler temperature. The correction for PCO_2 is based on a calculated decrease of 4.5% per degree Celsius. On the other hand, the pH increases 0.015 units per degree Celsius drop in temperature. This shift in pH is partially related to the

influence of buffers such as the imidazole moiety of histidine, but it is also related to the dynamics of the Henderson-Hasselbalch equation, $\text{pH} = \text{pK} + [\text{HCO}_3^-]/(0.03 \times \text{PCO}_2)$.

Because alkalosis and hypocarbia trigger a decrease in cerebral blood flow (CBF), some investigators have suggested the addition of CO_2 during hypothermia to compensate and to keep the pH unchanged (pH-stat strategy). In 1987, Murkin and coworkers⁵ confirmed that pH-stat management results in a greater ratio of CBF to cerebral metabolic rate (CMRO_2) than alpha-stat management (i.e., no active correction of pH with hypothermia). Most agree that a pH-stat strategy is probably preferable in children, where increased CBF increases the rate of cooling and thus increases the chance of achieving uniform cerebral hypothermia.⁶ The rate of brain oxygen depletion during deep hypothermic circulatory arrest is also considerably slower with pH-stat strategy. As a result, pH-stat substantially prolongs the interval between the onset of arrest and the exhaustion of brain oxygen stores and may be associated with better clinical outcomes in this group.

In contrast, in adults, an alpha-stat strategy may provide greater cerebral protection during hypothermia on CPB.⁷ Alpha-stat management is certainly easier to accomplish, and a justification is that most cellular mechanisms are capable of maintaining intracellular pH despite fluctuations in extracellular conditions. Because excess CO_2 is added in a pH-stat strategy, brain acidosis may occur during rewarming, and, combined with decreased O_2 delivery after CPB, this may augment CNS injury in adults. Most importantly, as mentioned, a pH-stat strategy results in excessive CBF, which may increase embolic load. Finally, pH-stat strategy is associated with a decreased ability to maintain autoregulation at low pressures. Three randomized controlled trials have demonstrated a small but present benefit of alpha-stat strategy in terms of neurologic and neurocognitive outcome in adults, especially when CPB time exceeded 90 minutes and therefore evidence-based guidelines now support that patients undergoing moderate hypothermic CPB should be handled with an alpha-stat pH management (Class I, Level A).⁸

Hematocrit and Priming

In the 1960s, crystalloid (dextrose 5% in water, or D5W) in prime was introduced as an alternative to routine whole blood prime. An increase in efficiency of oxygenation and a decrease in end-organ complications were seen with this approach.⁹ Now hemodilution is commonly practiced in virtually all adult and pediatric cardiac surgeries, with the hematocrit (Hct) maintained between 20% and 25% during CPB. Hemodilution has a major effect on blood viscosity, primarily at the capillary level where the radius is small and the shear rate is low. Low flow at the capillary level increases viscosity of the blood, further increasing the resistance, but this effect is counterbalanced by the effect of hemodilution.

The drop in O_2 content at most levels of moderate hemodilution may be compensated by augmented cardiac output (CO), so total O_2 delivery ($\text{CO} \times \text{O}_2$ content of

blood) is increased. Hypothermia complicates the effects of hemodilution, as the decreased temperature causes increased viscosity and induces vasoconstriction.

The optimal Hct for CPB remains a topic of significant controversy. A post hoc assessment of the impact of low Hct on admission of cardiac patients to the intensive care unit (ICU) by Spiess and colleagues¹⁰ showed an inverse correlation between admission Hct and the risk of Q-wave myocardial infarction (MI). On the other hand, studies have demonstrated that an Hct of less than 20% may be associated with abnormal distribution of blood flow to organs, and that an Hct of less than 15% may lead to maldistribution of coronary flow away from the subendocardium in the presence of residual coronary stenosis.¹¹ Retrospective observational studies of consecutive patients undergoing isolated CABG have demonstrated that a lower minimum Hct is associated with a significantly increased risk of renal injury¹² and mortality.^{13,14} These relationships have also been demonstrated in patients with low Hct during CPB who did not receive any transfusion so as to differentiate that this was not an effect of blood products that these patients might otherwise receive.^{15,16} As excessive hemodilution also increases CBF, it may cause a parallel increase in microembolization and thus may theoretically be a contributor to neurologic damage after CPB and the increased risk of stroke observed with lower Hct on CPB.¹⁷

Most centers prime the CPB circuit with a solution of balanced salt with or without the addition of a colloid solution such as pentastarch. Infants and children often need blood added directly to the prime, depending on the anticipated Hct after initiation of bypass (calculated from standard nomograms). Other additives to the prime may include calcium, mannitol, and pharmacologic agents such as heparin and aprotinin. The patient's circulating volume and the pump prime volume mandate the minimum priming volume. Although the prime volume averages 1 liter, experienced practitioners can achieve as low as 200 mL in pediatric circuits.

Flow Rates, Perfusion Pressure, and Autoregulation

Flow is generally kept in the range of 2.2 to 2.5 liter/min/ m^2 to provide a margin of safety during CPB, because systemic blood flow distribution and O_2 consumption remain normal at this level. At normothermia, a target mean blood pressure of 50 to 70 mm Hg is used. (As a rule of thumb in adults, the mean pressure chosen should be equal to the patient's age.) The perfusionist can control the pressure by increasing or decreasing flow or by the addition of vasoconstrictors or vasodilators (inhalational anesthetics). At lower temperatures, a mean pressure of 35 mm Hg is still generally accepted as safe, but these findings are controversial.^{18,19}

Although the brain comprises only 2% of body weight, its metabolic needs demand 15% of the cardiac output, extracting as much as 25% of the delivered O_2 . Temperature is the most important element influencing CBF during CPB. As the temperature is dropped, the CMRO_2 decreases exponentially and the CBF decreases linearly (Fig. 63-5). As a consequence, the ratio of CBF to CMRO_2

FIGURE 63-5 ■ The effect of hypothermia on cerebral metabolic rate (CMRO₂) and cerebral blood flow (CBF).

FIGURE 63-6 ■ Through autoregulation, cerebral blood flow (CBF) is constant from cerebral perfusion pressure (CPP) 40 to 140 mm Hg. Other factors that independently affect CBF include PaCO₂ and PaO₂. (Modified with permission from Kelly BJ, Luce JM: Current concepts in cerebral protection. *Chest* 103:1246–1254, 1993. Copyright 1993, American College of Chest Physicians.)

increases, resulting in “luxuriant” flow, further facilitated by hemodilution.

Autoregulation of CBF is also related to changes in perfusion pressure. At normothermia, a mean pressure of 50 mm Hg is the threshold at which the brain autoregulates flow, but with hypothermia (26°C), the threshold drops to 30 mm Hg (Fig. 63-6). At deep hypothermia (<20°C), there is a loss of pressure-flow autoregulation, as severe temperature reductions impair cerebral vascular relaxation and changes in cerebral perfusion pressure alone result in corresponding proportional changes in CBF. Other factors that influence CBF and CMRO₂ include blood viscosity, intracranial pressure and central venous pressure (CVP), and the blood gas status (pH, PaCO₂, PaO₂). CBF varies linearly with the PaCO₂, in the range of 20 to 80 mm Hg, whereas a PaO₂ of less than 50 causes cerebral vasodilation, which overrides pressure-flow autoregulation.

A

B

FIGURE 63-7 ■ **A**, A double roller pump has rotating arms oriented at 180 degrees like spokes on a wheel. Spool-shaped rollers are located at the ends of the arms. A length of tubing is locked inside a curved track at the outer circumference of a partial circle of 210 degrees. **B**, A typical centrifugal pump has a cone-shaped outer housing with an upper inlet and a single lower outlet. The inner chamber contains spinning concentric smooth cones or fins, mounted on a central impeller. Arrows indicate direction of blood flow.

Pumps

The two commonly used types of pumps for CPB involve either roller or centrifugal fluid propulsion. With the former, noninterrupted contact of the rollers with the tubing in the track results in the nonpulsatile nature of the flow (Fig. 63-7A). Flow is calculated from the RPM of the roller pump knowing the diameter of the tubing and thus precisely the volume displaced. A low compression will result in inadequate flow, whereas excessive compression may aggravate hemolysis and tubing wear. Other complications associated with the use of the roller pump include (1) cavitation caused by excess pressure and (2) spallation (the release of particles from the inner surface).

Centrifugal pumps (see Fig. 63-7B) are a popular alternative to the roller pump, particularly in pediatric cardiac surgery. A rotating impeller spins at 2000 to 5000 revolutions per minute on a small bearing, or the blades are magnetically suspended. This creates a vortex that draws blood into the pumphead and thrusts it to the oxygenator.

The advantages of this device include its relatively small priming volume and its reliability (with fewer technical failures as compared to a roller pump device). Whereas with a roller pump, venous drainage to the reservoir from the patient is dependent on gravity drainage, centrifugal pumps are not constrained by this action. The flow in a centrifugal pump is preload and afterload dependent, and it is not predictable solely based on the calculated revolutions per minute, so an in-line flowmeter is essential. Aside from their expense (\$150 per case), these devices are susceptible to air locks, thus requiring vigilance by the perfusionist. On the other hand, this may be protective, because there is less chance of pumping large volumes of air into the patient via an inadvertent leak, and the lines cannot be overpressurized with distal obstruction, as occurs with roller pumps. These devices are also not valved, and if rotation stops without clamping the outflow, rapid retrograde flow from the arterial line occurs in milliseconds, potentially exsanguinating the patient. Finally, roller pumps can be operated manually, but a power outage with a centrifugal pump can be a disaster.

A recent meta-analysis comparing roller versus centrifugal pumps for CPB, which included 18 randomized controlled trials with 1868 patients (predominantly isolated CABG), identified no significant difference for hematologic variables, blood loss and transfusions, neurologic outcomes (albeit not amenable to pooled analysis), or mortality rate.²⁰

Cardiotomy

Cardiotomy blood is the extravascular blood collected in the thoracic wound during CPB. In general, blood from the wound cavity is aspirated through a sucker device and transferred to a cardiotomy reservoir. Because of the close proximity of tissues in the wound and the potential for particulate matter to be collected, a filter and a defoaming chamber are incorporated into the cardiotomy reservoir. Mechanical injury, such as hemolysis, may result from the air-blood interface at the sucker, as well as from the compressive effects of the roller pump. Other mechanical complications from cardiotomy suction include the formation of particulate emboli, including fibrin, macroaggregates of denatured proteins and lipoproteins, fat globules, platelet and leukocyte aggregates, calcium, cellular debris, talc, and suture material.

Cardiac Venting

Cardiac venting involves the active aspiration of blood from the heart, thus creating a bloodless field to facilitate visualization. Venting in some form is necessary in virtually all cardiac operations involving CPB, primarily to aid visualization but also to avoid chamber distention. When the aorta is cross-clamped and the native coronary collateralization remains, particularly related to bronchial artery flow and return from the thebesian veins. Blood flow can also occur through the heart as a result of continued transit of blood through the right heart, through the lungs, and into the left heart. Potential sites for

cardiac venting include the pulmonary artery, the superior pulmonary vein, the left atrium, the left ventricle, and the ascending aorta.

Cannulation

Venous Cannulation

Siphonage generates the negative pressure necessary to draw blood from the venous circulation. The determinants of drainage include the height of the patient above the venous reservoir, the patient's blood volume, the resistance of the tubing, and the cannula dimensions (as this is the narrowest part of the venous return). Augmented venous return refers to the use of either a pump (e.g., centrifugal) inserted in series between the venous line and the reservoir (kinetic-assisted venous drainage) or the application of a vacuum to a closed hard-shell venous reservoir (vacuum-assisted venous drainage).

In most cases of cardiac surgery, venous cannulation is directly through the right atrium. Bicaval cannulation refers to the use of two single-stage cannulas introduced into the superior vena cava (SCV) and the inferior vena cava (IVC), usually through the right atrial wall. Cavoatrial cannulation involves the use of a two-stage venous cannula, inserted through the right atrium in the region of the atrial appendage, with the tip of the cannula directed into the IVC. The cannula is constructed with a fenestrated basket at the level of the right atrium to allow collection of blood from the coronary sinus and from the SVC. Bicaval cannulation is used when an "airless" right atrium is required, such as in tricuspid valve surgery. It is also preferred in mitral valve surgery, when distortion of the right atrium with retraction may lead to a compromise in SVC blood return and a rise in the CVP. Placing tourniquets around the SVC and IVC during bicaval cannulation allows the institution of *total* as opposed to *partial* bypass. With partial bypass, some return of venous blood still takes place through the tricuspid valve and subsequently through the pulmonary circulation. Occasionally in some pediatric cases or in complex adult or reoperative surgery, it is necessary to directly cannulate into the innominate vein, the jugular vein, or the SVC. Alternative sites for venous access include the femoral, iliac, and axillary veins.

Cannula size should be chosen so that the anticipated pressure drop across the cannula is equal to, or less than, the siphonage pressure that is applied based on the height of the patient above the pump and on the patient's blood volume. If this principle is not followed, the CVP might increase, which could compromise cerebral perfusion pressure. Like aortic cannulas, venous cannulas are often wire reinforced, and the tips may be constructed of thin metal to optimize the inner-to-outer-diameter ratio.

Arterial Cannulation

Oxygenated blood is returned to the arterial circulation through specially designed arterial cannulas, which come in a variety of configurations. Cannula characteristics include their length, diameter, orientation of the tip (straight or right angle), presence of a flange, and distal

tapering. The arterial cannula is the narrowest portion of the CPB circuit after the oxygenator, and thus it is the site of the highest potential gradient; gradients in excess of 100 mm Hg can be associated with hemolysis. Finally, although the size and shape of the cannula have not been shown to influence the rate of transcranial Doppler-detected microemboli,²¹ design concepts such as tips to diffuse the sand-blasting effect of flow, differential flow to the arch vessels, and distal baskets to capture debris have been introduced to minimize, at least theoretically, the potential that the cannula may contribute to atheroemboli.

Complications of ascending aortic cannulation include aortic intramural hematoma and dissection (0.01% to 0.09%), atheroemboli either directly from the cannula or from a jet effect, carotid hypoperfusion, air embolism, injury of the back wall of the aorta, and misdirection of the tip of the cannula either posteriorly across the aortic valve (causing severe aortic insufficiency) or anteriorly into the arch vessels or against the wall of the aorta. Femoral cannulation is most commonly used in situations of reoperative surgery and anticipated substernal adhesions. The dissection rate with femoral cannulation is between 0.2% and 3%. Retroperitoneal access to the iliac vessels by suprainguinal retroperitoneal dissection may also be necessary. Another attractive approach, particularly in cases of aortic dissection, involves the use of axillary cannulation. This artery is less likely to be involved with atherosclerosis than are the lower extremities. There is exceptional collateral flow compared with the leg vessels, so the procedure is well tolerated and only infrequently results in limb ischemia. The direction of flow during axillary cannulation also favors noncerebral embolization should there be atherosclerotic disease in the arch of the aorta, and there is less chance of inappropriate extension and malperfusion of a false lumen in cases of aortic dissection.²² Complication rates of this procedure are minimized by cannulation through a short tube graft, anastomosed in an end-to-side manner to the axillary artery, as opposed to direct cannulation.

One of the most perplexing problems related to arterial cannulation is the management of patients with extensive aortic calcification. With bypass grafting, the use of off-pump surgery with a "no-touch" technique may be considered. Alternatively, femoral or axillary cannulation can be used with fibrillatory arrest, left heart venting, and arterial grafting. A third potential strategy involves the threading of a long cannula beyond the atheroma, into the descending thoracic aorta. Borger and Feindel²³ demonstrated that cannulation beyond the cerebral vessels with a long cannula decreased the count of cerebral emboli as detected by transcranial Doppler. Finally, in extreme cases, surgeons may cannulate the apex of the left ventricle with an armored venous cannula passed through the apex into the ascending aorta across the aortic valve. Epi-aortic scanning has been advocated as a means to detect problems with the aorta and, when used consistently, may alter surgical management in terms of cannulation and clamp site as well as offering the option to proceed with off-pump surgery.²⁴ This modality is effective in trained hands and more sensitive than transesophageal echocardiography (TEE) and

digital palpation. Guidelines strongly support intraoperative TEE or epi-aortic ultrasound scanning of the aorta to detect nonpalpable plaque (class I, level B), and reduce the cerebral embolic load (class IIa, level B) in patients at high risk of adverse neurologic events.²

PATHOPHYSIOLOGY

Noncellular Response

The pathophysiology of CPB relates to the unique responses that occur when blood contacts a biomaterial surface (biomaterial-dependent processes), non-contact-related processes such as cardiotomy blood collection and the effect of nonpulsatile flow. Within milliseconds of the blood's contacting the synthetic surfaces of the CPB circuit, plasma proteins become adsorbed to the biomaterial. Although the amount, composition, and conformation of protein adsorption may differ between surfaces, there is no surface on which this process is completely inhibited, and each surface has a characteristic blood-adsorption pattern. Further exposure of the surface to blood results in activation of proteins of the contact activation system (Fig. 63-8). This system comprises four primary plasma proteins: factors XII and XI, prekallikrein, and high-molecular-weight kininogen (HMWK). In the presence of the negatively charged biomaterial, a conformational change occurs in factor XII that permits its activation in the presence of prekallikrein and HMWK. Factor XIIa activates factor XI and initiates the intrinsic coagulation pathway, with the subsequent generation of thrombin and the cleavage of fibrinogen to produce fibrin, which is cross-linked by activated factor XIII. Factor XIIa also activates prekallikrein to form kallikrein within seconds of the start of bypass. Kallikrein catalyzes the conversion of HMWK to bradykinin and plays a role in the activation of the fibrinolytic system. Bradykinin has a very short half-life in the plasma because of its rapid metabolism by angiotensin-converting enzyme in the pulmonary circulation²⁵ and by the vascular endothelium.²⁶ It is believed to be a key mediator of increased

FIGURE 63-8 ■ Proteins of the contact activation system. *FXI*, Factor XI; *FXIa*, activated factor XI; *FXII*, factor XII; *FXIIa*, activated factor XII; *HMWK*, high-molecular-weight kininogen.

capillary permeability and the development of tissue edema. Bradykinin mediates vasodilation by stimulating the release of endothelial nitric oxide,²⁶ and it may also be an important mediator of cerebral ischemia.²⁷

Activation of the fibrinolytic system during CPB is evidenced by increased levels of tissue plasminogen activator (tPA) and plasmin-antiplasmin complexes. Thrombin and bradykinin contribute to fibrinolysis through the direct activation of endothelial cells and the release of tPA, which further increases plasmin generation.²⁸ Kallikrein activates the fibrinolytic system through its role in catalyzing the conversion of plasminogen to plasmin and the activation of pro-urokinase.²⁹ Another mechanism by which plasmin generation may contribute to bleeding is through its direct effect on platelet receptors during CPB.³⁰

The complement system is activated through several mechanisms during CPB (Fig. 63-9). First, the third component of complement (C3), adsorbed to the CPB surface after releasing the potent chemoattractant C3a, is joined by the inactive factor B and properdin to produce the active proteolytic enzyme C3 convertase. C3 convertase cleaves the fifth component C5 to generate the active fragment C5a and the terminal complement complex C5b-9. Other mechanisms for complement generation through alternative pathways include the direct cleavage of C5 by kallikrein to produce C5a and the direct cleavage of C3 by plasmin. Complement generation has also been reported to be induced directly by endotoxin or directly by the cytokines tumor necrosis factor (TNF) and interleukin (IL)-6.³¹ Heparin-protamine complexes formed at the end of CPB activate the classical complement pathway, as does immunoglobulin bound on the biomaterial surface, which complexes with C1q.³²

The generation of complement plays a key role in the recruitment of leukocytes, the upregulation of neutrophil activation markers, and the production of cytokines. Studies by Kirklin's group³³ confirmed that the incidence and degree of deranged function of the heart, lung, and kidney after CPB could be related to the raised plasma concentration of the complement fragment C3a. Furthermore, inhibition of production of terminal complement complex by a protease inhibitor was associated with

a significant reduction in the deleterious effects of ischemia-reperfusion to the myocardium after CPB.³⁴

Nitric oxide (NO) is a potent inflammatory mediator whose production is increased after CPB. Endogenously produced NO may cause tissue injury through formation of toxic peroxynitrites, activation of cyclooxygenase, and DNA deamination. Studies have reported a significant increase in inducible nitric oxide synthase (iNOS) expression in human lung after CPB, which may be related to cytokine release (e.g., TNF, IL-1, IL-6).³⁵ This induction has also been shown to be associated with myocardial depression secondary to reperfusion injury.³⁶

Finally, CPB initiates a cascade of events that results in cytokine release. This response may be triggered by changes in bowel mucosal blood flow and by bacterial translocation, as lipopolysaccharide (LPS) concentration increases by 100% immediately on CPB institution, with another significant increase seen after aortic cross-clamp release. LPS induces a broad range of immunologic effects and is considered the most potent stimulator of TNF- α production from macrophages. TNF induces monocyte IL-1 production, and TNF and IL-1 in concert induce IL-6 production and release.³⁷ Peak concentration of IL-6 occurs a few hours after the end of CPB, with a gradual decrease toward preoperative levels in the following 24 hours.³⁸

Investigators have demonstrated a correlation between the release of IL-6 and myocardial dysfunction after CABG surgery.³⁹ TNF may be released locally in the myocardium, and this may be related to postischemic myocardial stunning.⁴⁰ Jansen and coworkers⁴¹ demonstrated that a rise in TNF can be detected after release of the aortic cross-clamp. TNF, IL-6,⁴² and IL-8 levels also correlated with the duration of the cross-clamping and the degree of myocardial injury as reflected by increased levels of serum troponin.⁴²

Cellular Activation: Platelets, Endothelial Cells, Leukocytes

Although the cellular events during CPB are influenced by the dynamic nature of the activation by the unique soluble products produced at the biomaterial, they are

FIGURE 63-9 ■ Mechanisms of complement activation during cardiopulmonary bypass (CPB). *IL-6*, Interleukin 6; *TCC*, terminal complement complex; *TNF*, tumor necrosis factor.

more significantly affected by the composition of proteins adsorbed on the nonendothelial surface. Surface-adsorbed fibrinogen is the key mediator of platelet accumulation on foreign materials. Platelet adhesion to artificial surfaces increases with increasing surface concentration of adsorbed fibrinogen if the bound fibrinogen maintains a conformation such that the functional domains of the molecule are recognizable by the activated platelet glycoprotein (GP) IIb/IIIa receptor. This latter interaction is probably the most important factor mediating platelet consumption during CPB. The three-dimensional conformation of adsorbed fibrinogen also influences the degree of platelet accumulation.

CPB is associated with a consistent increase in the proportion of activated circulating platelets. Agonists of platelet activation during CPB include thrombin, adenosine diphosphate (ADP), heparin, protamine, activated complement, and plasmin. Physical activators of platelets include hypothermia and the process of cardiotomy blood collection. The latter effect may be related to the air-blood interface, the blood-tissue interface, or the exposure to thrombin generation in cardiotomy blood.

The most consistently documented measure of CPB-related activation is an increase in the expression of guanosine monophosphate (GMP)-140 (P-selectin).⁴³ Platelet GP IIb/IIIa is also likely activated.⁴⁴ Platelet microparticles, which may be highly procoagulant, can be consistently detected by flow cytometry after CPB.⁴⁵ Other platelet products increased after CPB include β -thromboglobulin and platelet factor 4 (PF4).⁴⁶

In clinical CPB, thrombocytopenia is seen commonly, with platelet counts dropping more than 50%, resulting not only from platelet adhesion to surfaces but also from hemodilution, platelet aggregate formation, and the formation of platelet-leukocyte complexes. With these changes, it is not surprising that the most predictable alteration in hemostatic function observed after CPB is platelet dysfunction. Clinical reflectors of this process include a universal prolongation of the bleeding time that is directly related to postoperative blood loss.⁴⁷ Platelet aggregation to ADP and epinephrine is consistently abnormal,⁴⁸ and there is decreased response to thrombin agonist receptor peptide (TRAP), consistent with a decrease in receptor sensitivity.⁴⁹

The endothelial layer is the front line of many of the cellular responses related to CPB. It is now evident that it is the activation of these cells that mediates many of the injurious processes such as reperfusion injury. The generation of cytokines is a major contributor to endothelial cell activation, primarily because they upregulate receptors necessary for neutrophil-endothelial cell binding.⁵⁰ Endothelial cells undergo upregulation of intercellular adhesion molecule (ICAM) and E-selectin. The latter binds to the integrin CD11a/CD18 present on resting polymorphonuclear leukocytes (PMNs). PMNs and monocytes may be activated with upregulation of the integrin CD11b/CD18 complex,⁵¹ which also binds ICAM on endothelial cells.⁵² Further cellular activation is evidenced by the acute rise in soluble P-selectin, with a concomitant fall in soluble E-selectin, and by increased elastase release.⁵³ Leukocytes interact with platelets during CPB as another means of systemic inflammation.

FIGURE 63-10 Mechanisms contributing to thrombin generation in cardiotomy blood. Heparin (Hep) levels are decreased as a result of (A) binding to wound surfaces and (B) binding to platelet factor 4 (PF4). Heparin is also ineffective because of (C) its inability to inhibit clot-bound thrombin. Thrombin generation occurs through other monocyte-dependent processes such as (D) tissue factor (TF) and (E) cathepsin/CD11b complex-mediated factor X (FX) activation.

Increased GMP140 on the platelet surface is essential to mediate complex formation of platelets and monocytes or PMNs.⁵² Monocyte-platelet conjugates increased from 18% to 44%, whereas PMN-platelet conjugates increased only slightly.⁵²

Nonbiomaterial-Related Activation

Exposure of cardiotomy blood to wound surfaces is probably the most important source of thrombin generation during CPB (Fig. 63-10). Two factors contribute to persistent thrombin generation in cardiotomy blood. First, heparin levels in the cardiotomy blood are well below those found in the systemic blood⁵⁴ because heparin may be bound to nonplasma components such as platelets or debris and it may be consumed by PF4. Furthermore, any heparin that is present is not capable of inhibiting thrombin completely, especially thrombin that is bound to fibrin.⁵⁵ Second, thrombin is generated via coagulation pathways other than the intrinsic pathway, and these are less effectively inhibited by heparin. Tissue factor on the wound surface and on the surface of activated monocytes contributes to coagulation,⁵⁶ as does the monocyte CD11b activation of factor X.⁵⁷ Cardiotomy blood also contributes to fibrinolysis induction⁵⁸; this may enhance systemic fibrinolysis after cardiotomy blood readministration and also has been proposed to be a factor in postoperative bleeding.

HEPARIN-PROTAMINE AXIS

Heparin: Pharmacology, Dosage, and Complications

Heparin, derived from bovine or porcine intestinal mucosa, is a glycosaminoglycan composed of chains of alternating residues of D-glucosamine and uronic acid. Heparin is commonly used in its unfractionated form

(UFH) consisting of a spectrum of molecular weights between 1000 and 30,000 Da with a mean of 15,000. ATIII is a natural inhibitor of thrombin, but heparin, acting as a cofactor, accelerates this action more than 4000-fold. Heparin's effect is accounted for by a unique pentasaccharide sequence with a high-affinity binding sequence to ATIII. There is also an 18 pentasaccharide unit fraction that allows for simultaneous binding of ATIII and thrombin. Heparin is then able to dissociate from this ternary complex to be reused in the circulation. UFH-ATIII complexes can catalyze the inhibition of factors IIa (thrombin), IXa, Xa, and Xia,⁵⁹ but they have little effect on factor XIIa.⁶⁰ Heparin's other actions as an anticoagulant include the facilitation of thrombin inhibition by heparin cofactor II, which inhibits the extrinsic pathway by heparin-mediated release of tissue factor pathway inhibitor. Finally, there is evidence that heparin's principal inhibitory effect on coagulation is through the inhibition of thrombin-induced activation of factors V and VIII.⁶¹

The clearance of heparin is influenced by its molecular size, with higher-molecular-weight species being removed from the circulation more rapidly than the lower-molecular-weight species. UFH is cleared through two phases: a rapid saturable phase and a slower phase of first-order mechanism; thus, anticoagulant response is not linear but increases in intensity and duration with increasing dosage.⁶² After injection, UFH is bound by a number of plasma proteins, including histidine-rich glycoprotein, PF4, vitronectin, fibronectin, and von Willebrand factor (vWF). This contributes to the variability of anticoagulant response to fixed-dosage heparin and the laboratory phenomenon of heparin resistance. The binding of UFH to endothelial cells and macrophages also contributes to its complicated pharmacokinetics.

During CPB, heparin is generally used in generous dosages of up to 300 U/kg, with an aim to achieve and maintain a target activated clotting time (ACT) of 400 to 480 seconds. This rather primitive test, although automated, involves the addition of an aliquot of whole blood to a test tube containing a blood activator (Celite or kaolin). In the Hemochron ACT device (International Technidyne Corp., Edison, NJ), when a clot forms, resistance to movement of a small magnet in the tube is detected and the timer stops. The HemoTec ACT device (Medtronic HemoTec, Englewood, CO), which uses kaolin as an activator, uses a plastic plunger for continuous mixing. The absence of plunger fall after a clot forms is detected photo-optically and the counter ceases.

Heparin may contribute to the bleeding diathesis after surgery, independent of its action as an antithrombotic. UFH may cause platelet dysfunction directly⁶³ or through its ability to bind to vWF. Heparin has an independent role as a profibrinolytic agent⁶⁴ before the initiation of CPB, which may be related to its activation of the kallikrein system.

Two forms of thrombocytopenia are related to heparin administration independent of CPB. The first is a benign reversible nonimmune thrombocytopenia, which immediately responds to the discontinuation of heparin and may be related to direct weak activation of platelets by heparin. The second, more serious reaction is an

IgG-mediated immune thrombocytopenia referred to as heparin-induced thrombocytopenia and thrombosis (HITT). The syndrome is secondary to platelet activation from an IgG that binds the FcγII receptor.⁶⁵ The heparin-PF4 complex on the platelet surface is the responsible target antigen. A secondary thrombogenic diathesis may result from platelet activation related to microparticle release.⁶⁶

HITT usually begins 5 to 10 days after the commencement of heparin therapy, but recent data have suggested that it can be detected within a mean of 10 hours of commencement of heparin in patients with previous exposure. This rapid response is not the result of an anamnestic immune response but rather that these patients continue to have circulating antibodies for up to a maximum of 100 days.⁶⁶ In general, 1% of heparinized patients will develop HITT at 7 days and 3% at 14 days.⁶⁷ Although thrombocytopenia may be evident, the surgeon must be wary of a normal platelet count in the postoperative period in the presence of unexplained thrombosis, when reactive thrombocytosis should be evident.

The diagnosis of HITT should be considered with a positive ELISA test for HITT along with an intermediate to high pretest probability score. This pretest probability score, known as the "4 T's" places weighted values on various aggregated factors, including the level of thrombocytopenia, timing of platelet count fall, thrombotic events, and ruling out other possible causes of thrombocytopenia.⁶⁸ The ELISA is highly sensitive but not specific for HITT and, if strongly suspected, the disease should be confirmed by the measurement of the release of radiolabelled serotonin from donor platelets after patient serum exposure.⁶⁹ It is of note that compared to other patients exposed to heparin, for some reason cardiac surgery patients more frequently have positive ELISA testing whereas a fewer percentage have actual HITT.⁶⁸

Surgical approaches to patients with HITT depend on the degree of urgency of the anticipated procedure. In elective situations, when surgery for patients with a history of HITT can be postponed (>100 days), heparin administration should be the primary strategy (Fig. 63-11).⁷⁰ If the surgery cannot be postponed, avoidance of CPB with off-pump techniques may be considered, but some form of anticoagulation is still necessary during anastomosis. Each institution should develop a strategy for the emergency management of CPB in the presence of HITT. A platelet-"paralyzing" agent such as prostacyclin may be used with careful titration of the drug to optimal platelet aggregation inhibition to minimize the attendant hypotension.⁷¹ Of the alternatives to UFH, low-molecular-weight heparin (LMWH) is not suitable as there is greater than 90% immune cross-reactivity with UFH, and CPB with LMWH is associated with significant bleeding.⁷² The heparinoid danaparoid (Orgaran, NV Organon, The Netherlands) has less than 10% antibody cross-reactivity and less than 5% clinical cross-reactivity⁷³ and thus may be useful, but no neutralizing agent is available and because of danaparoid's long half-life, significant bleeding must be anticipated after its use.⁷⁴ Ancrod (Viprinex, Abbott Laboratories, Canada) is a defibrinogenating agent derived from snake venom. The clinical experience with this agent is limited, and its

FIGURE 63-11 ■ Temporal pattern of heparin-induced thrombocytopenia in relation to previous treatment with heparin. None of the patients whose prior heparin treatment had occurred more than 100 days earlier had rapid-onset thrombocytopenia. drawbacks include that it blocks neither thrombin generation nor platelet activation, it is antigenic, and a delay of 12 hours for the full effect is required.

ATIII-independent thrombin inhibitors such as hirudin, bivalirudin, and argatroban hold promise as the best alternatives for CPB management in these difficult situations. Recombinant hirudin (Refludan, Hoechst, Kansas City, MO) binds the catalytic and fibrinogen binding sites of thrombin. It has been successfully used in clinical CPB⁷⁵ and in deep hypothermic circulatory arrest.⁷⁶ This drug can be monitored using the ecarin clotting time.⁷⁷ Argatroban also specifically binds the catalytic site of thrombin. Its potential benefit over hirudin relates to its shorter half-life (15 to 30 minutes, compared with 30 to 60 minutes for hirudin), which compensates for its lack of a reversing agent. This drug has been used in CPB,⁷⁸ but greater experience is needed before giving it a universal recommendation. Bivalirudin has been demonstrated as safe as heparin for on-pump surgery,⁷⁹ and it may be easier to use than hirudin because of its shorter half-life.⁸⁰ Updated guidelines recommend the use of bivalirudin over other nonheparin anticoagulants or heparin plus antiplatelet agents (Grade 2C) for patients with acute or subacute HIT requiring emergent cardiac surgery⁸¹; however, this drug is not safe if circulatory arrest or low flow is anticipated, because clotting will occur in the oxygenator.⁸²

Protamine: Pharmacology, Complications

Protamine is a polycationic protein derived from salmon sperm. The positive charges on protamine combine ionically with the negative moieties of the heparin molecule, separating it from ATIII and producing a stable precipitate that is rapidly cleared from the circulation. The drug is given intravenously at a fixed ratio of 1 to 1.3 mg/100 U administered heparin. The most common problem

related to protamine is heparin rebound, which is a frequent cause of postoperative bleeding. This phenomenon is related to the delayed desorption of heparin from plasma proteins and endothelium after the first dose of protamine has been cleared. It usually becomes evident 2 to 3 hours after arrival in the ICU, and its presence is reflected by increasing chest tube losses accompanied by a new prolongation of the ACT or thrombin time. The problem can be obviated by the routine addition of a protamine drip after surgery.

Protamine has a direct antithrombin effect; however, this effect is seen only at extremely high dosages. Preformed platelet-activating anti-protamine-heparin antibodies have been demonstrated to be causative in cases of unexplained early and prolonged postoperative thrombocytopenia.⁸³ Hypotension is another common consequence of protamine administration, particularly with rapid intravenous administration. The mechanism of this rate-related effect is not known, but its magnitude is greater in situations of low preload and afterload. Protamine may also be responsible for several idiosyncratic hypotensive reactions. Anaphylactoid reactions are mediated primarily by complement and histamine. Anaphylactic reactions involve the IgE-mediated release of histamine and other vasoactive mediators. Both reactions are characterized by edema, hives, and bronchospasm in the presence of low filling pressures. The most serious form of protamine-related hypotension is catastrophic pulmonary vasoconstriction. In contrast to the other two forms of idiosyncratic protamine reactions, this syndrome may be associated with bronchospasm, and with pulmonary hypertension with an elevated CVP. The mechanism is probably related to IgG release with activation of complement, activation of PMN, and release of platelet thromboxane A₂.⁸⁴ Theoretically, patients at risk for protamine reactions include those with previous vasectomy, previous exposure to protamine, or previous exposure to protamine-containing insulin.

When problems with protamine have been detected in advance, the cardiac surgeon must consider alternative strategies. In minor cases with low risk, premedication with steroids (at least 12 to 24 hours in advance) and histamine blockers may suffice. A small test dose (5 mg) should be given to ensure safety. Avoidance of neutralization after the massive dosages required for CPB may be difficult because of the prolonged half-life of heparin. Recombinant PF4 has shown promise as an alternative to protamine.⁸⁵

The rationale for heparinizing to an ACT of between 400 and 480 seconds during CPB is based on early work that demonstrated that at this level of ACT, no gross evidence of thrombosis occurred in the circuit. However, many researchers have expressed doubt about the validity of using ACT as gold standard for anticoagulation during CPB. In particular, there is clear evidence that the ACT does not reflect the heparin level accurately, particularly after a long duration of CPB, and that other factors, such as hypothermia, hemodilution, and drugs, may contribute (Fig. 63-12).⁸⁶ The Hepcon device (Medtronic HemoTec, Englewood, CO) is composed of a series of ACT cuvettes containing incrementally increased protamine dosages that can be used to precisely calculate the circulating heparin level. Patient-specific preoperative standard curves with target heparin concentrations can be precisely calculated. It is interesting that with this technique, overall heparin requirements are higher (25%). However, factor consumption during CPB is decreased, most likely related to an inhibition of low-grade coagulation. In clinical trials, this technique also resulted in a shorter bleeding time on arrival in the ICU that was associated with decreased blood product use.⁸⁷ A fixed-effects meta-analysis model analyzing standard versus titrated dosing of protamine has confirmed significantly less postoperative bleeding with the latter strategy.⁸⁸

PHARMACOLOGIC AND HEMATOLOGIC ADJUNCTS TO MINIMIZE CONSEQUENCES

Randomized controlled trials have confirmed that leukocyte depletion successfully decreases IL-2 and C3a⁸⁹ and IL-6 and TNF.⁹⁰ This strategy also appears to minimize myocardial damage and to decrease the incidence of perioperative atrial fibrillation.⁸⁹

Steroids are widely used for the suppression of inflammation in chronic inflammatory diseases. During CPB, steroids blunt complement activation, upregulation of glycoprotein CD11b,⁹¹ and the release of histamine,⁹² TNF, IL-8,⁹³ IL-6,⁹⁴ and neutrophil elastase.⁹⁵ Finally, steroids reduce airway NO concentrations during CPB⁹⁶ compatible with inhibition of bronchial epithelial iNOS expression. Steroids have also been demonstrated to be associated with decreased CK MB.⁹⁷ The inhibition of these aspects of inflammation may explain the stabilizing effect of these drugs on hemodynamics after CPB. Contrary to expectations, steroid use has not been demonstrated to be associated with postoperative wound infection in cardiac surgery.⁹⁸ Three meta-analyses have failed to demonstrate any other major benefits in terms of mortality and morbidity other than a decrease in the incidence of postoperative atrial fibrillation.⁹⁸⁻¹⁰⁰ Whereas routine administration of steroids for adult cardiac surgery patients remains controversial, this is not the case for pediatric surgical patients; at least 40% of centers routinely administer steroids, particularly in neonates and cases involving deep hypothermic circulatory arrest.¹⁰¹

Although aprotinin has anti-inflammatory effects, its use has come under significant scrutiny as a result of ongoing debate regarding its possible prothrombotic effects.¹⁰²

FIGURE 63-12 ■ Time course of physiologic and hematologic mean values for patient with cardiopulmonary bypass (CPB). Mean values for activated clotting time (ACT) expressed in seconds per 100 for both Hemochron (HC ACT) and Hepcon (HT ACT) assays. Plasma-equivalent heparin concentration (WB HC) and anti-Xa plasma heparin concentration (Xa HC) expressed in units per milliliter. Hematocrit (Hct) values expressed as percent divided by 10 (%/10), and core body temperature (Temp) expressed in degrees centigrade divided by 10 (°C/10). Mean values for derived physiologic and hematologic variables are plotted as a function of time in minutes. Phase II time points begin before heparin administration and then 10 minutes after each of the following: heparin administration (A), initiation of CPB (B), achievement of hypothermia (C), rewarming (D), and immediately before discontinuation of CPB (E). Copyright 1994, Mosby-Year Book Inc.).

BIOMATERIAL-DEPENDENT STRATEGIES TO MINIMIZE BLOOD ACTIVATION

A biomaterial-dependent strategy involves the choice of a CPB circuit composed of a biomaterial with enhanced biocompatibility. The quest for an ideal biomaterial substrate for the construction of CPB circuits has culminated in three types of surface modifications that either have been tested in human trials or are on the verge of clinical evaluation.

Biomembrane Mimicry

A biomaterial has been developed that mimics the anti-thrombotic behavior of natural cell membranes. It is coated with a derivative of phosphorylcholine, which is the major lipid head group component found on the outer surface of biologic cell membranes.¹⁰³ In vitro data have demonstrated the efficacy of this modified surface (Memsys, Sorin Biomedica) in inhibiting fibrinogen adsorption and platelet deposition. Other biocompatible-coated CPB circuits include hyaluronan (Vision HFO-GBS-HF, Gish Biomedical, Rancho Santa Margarita, CA) based heparin free coating and Bioline coating (Quadrox, Maquet-Dynamed, Hirrlingen, Germany). Differences at the molecular level may exist between phosphorylcholine-coated, albumin-heparin-coated, or synthetic polymer-coated circuits, but no significant clinical benefits between these systems have been observed other than a reduction in atrial fibrillation and a shortened ICU length of stay.¹⁰⁴

Heparin-Coated Circuits

There are two types of commercially relevant heparin-coated circuits. In the first group, heparin is bound so that it may be slowly released into the circulation from the surface. The original binding, pioneered by Gott and colleagues,¹⁰⁵ existed as a surface in which the heparin was ionically bound to benzalkonium attached to the substrate polymer. In the second group, heparin is immobilized permanently on the biomaterial surface by covalent bonding. Polyethylene oxide is used as a spacer group, as its hydrophilic character and its dynamic motion further inhibit platelet interactions. The Carmeda product (Carmeda, Medtronic, Minneapolis, MN) is a commercial example of this technology for CPB, in which heparin is covalently bound via an endpoint immobilization technique. The Trillium Biopassive Surface (Medtronic, Minneapolis, MN) is a similar covalent coating process involving two polymers on the substrate surface. The first polymer functions as a primer, strongly bonding to the surface of the substrate. The second polymer, which is bound to the primer coat, is composed of sulfate and sulfonate groups, the latter providing a negative surface charge, as well as polyethylene oxide chains covalently bound to heparin. BioLine (Jostra, Germany) is a hybrid surface (i.e., a combination of heparin-releasing and heparin-immobilized) in which heparin is adsorbed onto a layer

of immobilized polypeptides through a combination of ionic interactions and covalent bonds.

Convincing *in vitro* evidence of the thromboresistant behavior of heparin-coated surfaces led to the hypothesis that less intense anticoagulation would be required for CPB when heparin-coated circuits were used. Many of the early clinical trials compared outcomes after CPB in which heparin-coated circuits were combined with lower dosages of heparin (one third to one half) versus control (uncoated) circuits and standard heparin dosages (300 U/kg). Advantages included decreased perioperative bleeding and transfusion. In a large clinical trial reported by Aldea and colleagues,¹⁰⁶ an integrated blood conservation strategy that included heparin-coated circuits and decreased heparin dosing was applied. This approach resulted in decreased blood transfusion requirements and significantly improved clinical outcomes as measured by ICU and hospital lengths of stay and by duration of ventilatory support. This translated into cost savings of approximately \$1700 per patient.¹⁰⁷

Compelling as these clinical results are, neither thrombin generation nor fibrinolysis has been consistently demonstrated to be decreased during CPB with heparin-coated circuits in human trials, with either standard or decreased heparin dosages compared with standard (non-heparin-coated) circuits.¹⁰⁸ Therefore, it is difficult to justify decreasing the heparin dosage, given the potential risk of low-grade thrombosis. Also, any measured differences in a patient's clinical and biochemical outcomes may be related to differences in the amounts of administered heparin and not to the surface, as heparin itself can induce myriad cellular and biochemical changes such as fibrinolysis and platelet dysfunction.⁶⁴ As the dosage of the protamine must also be increased, it is anticipated that changes such as complement activation must be proportionally increased. In most clinical trials in which the same dosages of heparin are used with both heparin-coated circuits and standard circuits, little clinical benefit has been consistently demonstrated, except perhaps in high-risk patients.¹⁰⁹

Beneficial clinical impacts of heparin-coated circuits are almost entirely related to their intrinsic anti-inflammatory effect. What has been consistently demonstrated is the capacity of heparin-coated surfaces to decrease complement activation¹¹⁰ independent of the heparin dosage. Other demonstrated anti-inflammatory effects of heparin-coated surfaces include decreased leukocyte surface activation markers or receptors,¹¹¹ decreased cytokine production,¹¹² and decreased monocyte tissue factor.¹¹³ The anti-inflammatory action of heparin-coated circuits in the absence of coagulation inhibition may be related to its action as a selective "protein sink" for such proteins as HMWK.¹¹⁴ Surface-adsorbed HMWK may interact with antithrombin III in the presence of surface heparin to potentiate heparin-mediated inhibition of kallikrein.¹¹⁵

In summary, heparin-coated surfaces have been demonstrated to exhibit potent antithrombotic behavior in *in vitro* testing. Although there is no evidence of decreased thrombogenicity when used clinically, there is consistent evidence that inflammation related to complement activation is decreased, and this may be responsible

for the improvement seen in some clinical outcomes after CPB.

Surfaces with Modified Protein Adsorption

Another biomaterial-dependent strategy involves surfaces designed to modify protein adsorption characteristics. An example of this approach includes a new generation of biomaterials into which a surface-modifying additive (SMA) has been incorporated.¹¹⁶ The additive is a triblock-copolymer with polar and nonpolar polymer chains. During the manufacturing process, the SMA migrates to the surface of the base polymer, yielding a stable microdomain-like configuration. Although the mechanism of action by which SMA decreases blood protein and cellular activation is not precisely known, it is hypothesized that the alternating hydrophobic and hydrophilic regions of the microdomain surface lead to uniform adhesion of fibrinogen, so that all of the sites for potential platelet interaction with surface-bound fibrinogen are competitively blocked. A randomized controlled trial in which patients underwent CPB using a standard control circuit or a circuit prepared “tip-to-tip” with the SMA copolymer (SMA-CPB)¹¹⁷ showed striking changes in the effect of this surface on markers of coagulation, fibrinolysis, and platelet number and function. Thrombin generation was significantly decreased with SMA-CPB compared with controls, despite carefully matched heparin dosages in the two groups. Defraigne and coworkers¹¹⁸ in a larger clinical trial confirmed the same degree of platelet preservation with SMA-CPB and a similar decreased release of β -thromboglobulin. In addition, there was evidence of a decreased need for the transfusion of platelets and fresh-frozen plasma in the group with SMA-CPB circuits.

Terumo Corporation (Tokyo, Japan) developed a surface for CPB circuits with a biocompatibility profile similar to that of SMA, in that it was engineered to positively influence protein adsorption. Surfaces are coated with poly(2-methoxyethylacrylate) (PMEA), which has a hydrophobic polyethylene backbone, and its residue has mild hydrophilicity with no chemical functional groups such as -OH or -NH₂. It was predicted that as the outer side of the PMEA molecule is inactive chemically, the surface would have little tendency to react with blood components. Although clinical studies in humans are not available, promising data from in vitro and in vivo models support the potential improved biocompatibility of PMEA-coated surfaces.¹¹⁹ Analysis of the composition of the adsorbed protein layer on PMEA-coated surfaces demonstrated a striking decrease in the amount of adsorbed IgG. This finding correlated with platelet count preservation as compared with uncoated surfaces, as surface-bound IgG is a well-known platelet activator. The use of the PMEA circuit was also associated with a significant decrease in CD35-positive monocytes during CPB.¹²⁰ Decreased adsorption of immunoglobulin is again probably the causative mechanism for decreased complement activation. Plasma bradykinin levels are decreased with PMEA, as are thrombin-antithrombin III levels.¹¹⁹

RELATED ORGAN DERANGEMENTS

Neuroendocrine Response

The changes in neuroendocrine response related to CPB are different from those observed in noncardiac surgery. Hormones under hypothalamic-pituitary control include growth hormone, vasopressin, the adrenal cortical axis, and the thyroid hormone system. Growth hormone increases significantly during and after CPB.¹²¹ Vasopressin is a key regulator of renal water excretion and peripheral vascular resistance, and it may contribute to endothelial activation through release of vWF.¹²² Marked increases in vasopressin are seen after cardiac surgery with CPB, with the elevated levels persisting for hours.¹²³ This may be a protective effect, as depressed levels postoperatively are associated with vasodilatory shock.¹²⁴

There is a definite increase in adrenocorticotrophic hormone with CPB.¹²⁵ Total plasma cortisol concentrations typically decrease immediately on initiation of CPB as a consequence of hemodilution, but later values return to normal or higher than baseline accompanied by parallel increases in unbound cortisol, suggesting that this increase is related to increased total secretion.¹²⁶ Thyroid hormone dysfunction may play a role in the unique clinical response seen after CPB. Investigators have demonstrated that although thyroid-stimulating hormone remains normal, total and free T₃ drop and remains depressed for 24 hours after surgery, and reverse T₃ shows a fourfold rise at 8 and 24 hours postoperatively, thus producing a picture of sick euthyroid syndrome.¹²⁷

The catecholamines epinephrine and norepinephrine are both increased after CPB, which may be a contributing cause of severe postoperative hypertension.¹²⁸ The sympathetic system regulates glucose control at the level of the pancreas by controlling the release of insulin and glucagon. After the onset of CPB, blood glucose concentrations rise steadily in parallel with a drop in insulin levels, and insulin resistance is seen with higher than average dosages.¹²⁹ During and after CPB, renin levels increase, and this is associated with a rise in measured angiotensin II and aldosterone.¹³⁰

Among the locally released hormones, atrial natriuretic factor levels are probably reduced during CPB, especially in patients with preoperative elevations, but elevated levels may be seen in the presence of complications.¹³¹ Other locally released factors include histamine and serotonin, related to leukocyte and platelet activation.¹³² Histamine produces vasodilation and hypotension and may contribute to tPA release.¹³³ Its increase may be abolished by high-dose steroids and prostacyclin infusions.¹³⁴ Finally, CPB provides a consistent stimulus for prostacyclin and inflammatory eicosanoid formation, as evidenced by a marked increase in 6-keto-prostaglandin F_{1a} (a stable metabolite of prostacyclin),¹³⁵ thromboxane B₂,¹³⁶ and prostaglandin E₂ concentrations.¹³⁷

Central Nervous System Injury

Cerebral damage during heart surgery may be the complication most feared and respected by cardiac surgeons. Three major types of neurologic injury can occur after

CPB, but the distinction between them is blurred and they probably reflect a continuum of pathologic changes based on location, extent, and permanence of the injury.¹³⁸ Stroke is the easiest injury to recognize after CPB. Its incidence is difficult to pinpoint, but the best estimate is around 3% of patients undergoing CABG.¹³⁹ Based on the information from the Society of Thoracic Surgeons database, this complication is increased in women and in older adults. The incidence rises to 8% after isolated valve surgery and 11% after CABG combined with other surgery.¹⁴⁰ The cause is probably related to macroemboli from great vessels. Stroke is associated with a marked increase in 30-day mortality, and its occurrence doubles hospital stay and cost.¹³⁹

Delirium, seen in up to 3% of patients, is a state characterized by confusion and disorientation in the presence of an altered state of consciousness. This complication may increase hospital stay fivefold.¹⁴¹ Risk factors include increased age, hypertension, reoperative surgery, and a history of previous CABG, pulmonary disease, postoperative anemia, preoperative cognitive dysfunction, major depression, alcohol abuse, atrial fibrillation, prolonged intubation, and postoperative hypoxia.¹⁴²

Cognitive decline (postoperative cognitive deficit [POCD]) is defined as a change in memory, concentration, psychomotor speed, or dexterity. Although it may go unnoticed, sometimes the patient recognizes inability to complete previously facile tasks, or this inability may be recognized by the family. Quantitation depends on sensitive neuropsychological findings involving a reproducible battery of tests. A pooled analysis of six highly comparable studies by Van Dijk and colleagues¹⁴³ yielded a proportion of POCD after CPB of 22.5% (95% confidence interval, 18.7%-26.4%). Newman and colleagues,¹⁴⁴ Robinson and colleagues,¹⁴⁵ and Borowicz and colleagues¹⁴⁶ provide comprehensive reviews of studies of POCD after CABG; the reported incidences in larger studies range from 35% to 75% early postoperatively and 11% to 40% after more than 6 months. Sotaniemi and coworkers^{146a} found that even if the early postoperative changes disappeared, affected individuals were more likely to show early dementia 5 years later, as the underlying neuronal loss may make an individual more vulnerable to age-dependent cell loss in the future. Furthermore, Newman and coworkers¹⁴⁷ showed that patients demonstrating significant impairment early had reduced quality of life and were more likely to be impaired at 5 years, compared with patients not having early deficits.

One characteristic pathologic finding in canine and human cerebral tissue after CPB is referred to as small capillary and arteriolar dilations (SCADs) (Fig. 63-13). These are believed to be the sites of fat, particulate, or gas emboli.¹⁴⁸ Transcranial Doppler studies of patients during CPB have confirmed the frequent occurrence of embolic material in the cerebral circulation. Furthermore, the cerebral embolic load was found to be directly proportional to the length of CPB in an autopsy study by Brown and colleagues.¹⁴⁹ There is a direct correlation between POCD and retinal microemboli on fluorescein angiography.¹⁵⁰ Magnetic resonance imaging immediately after CABG has identified global cerebral swelling even in low-risk patients.¹⁵¹ Finally, there is strong

FIGURE 63-13 ■ Postmortem specimen of brain section illustrating small capillary and arteriolar dilation (arrows) after cardiopulmonary bypass. (Courtesy Dr. Dixon Moody, Wake Forest University.)

experimental evidence that cardiotomy suction blood may be the most important source of lipid emboli.^{152,153} Two recent clinical trials had different results as to whether processing cardiotomy blood has an impact on neurocognitive outcome, but this intervention did result in a significant increase in postoperative bleeding and transfusion, and thus it is debatable whether cardiotomy blood processing is safe.^{154,155}

Recently, however, the relationship of CPB to neurocognitive dysfunction after cardiac surgery has been called into question. First, several prospective randomized controlled trials have failed to show a clear benefit of off-pump compared with on-pump surgery in terms of the incidence of neurocognitive dysfunction.¹⁵⁶ Second, it was shown that nonsurgical control populations with coronary disease undergoing medical therapy or percutaneous intervention have the same rate of neurocognitive decline as those patients undergoing on-pump CABG.¹⁵⁷ Finally, the use of neurocognitive testing as a measure is debatable, as these evaluations were never designed as a pre-post test.

Pulmonary Dysfunction

Whereas 12% of patients develop mild lung injury after CPB, 1.3% develop frank acute respiratory distress syndrome (ARDS).¹⁵⁸ This problem is more common in older, obese adults and patients with low cardiac output or pulmonary hypertension, and after long CPB.¹⁵⁸ In most cases of CPB-related lung injury, full recovery occurs, but severe lung injury has a mortality of greater than 50%.¹⁵⁹ Clinical findings of lung injury include an increase in the alveolar-arterial oxygen pressure difference and the pulmonary shunt fraction, together with a decrease in the functional residual capacity. There may be increased pulmonary vascular resistance as well as evidence of increased lung permeability.¹⁶⁰ The cause of CPB-related lung injury does not appear to be related to hypoxia induced by partial CPB, because the bronchial circulation is adequate to prevent necrosis.¹⁶¹ There is, however, definite evidence of increased pulmonary inflammation with increased bronchoalveolar lavage

fluid-activated neutrophils,¹⁶² increased matrix metalloproteinases and myeloperoxidase levels,¹⁶³ and increased IL-8 and elastase,¹⁶⁴ all of which may contribute to breakdown of the pulmonary ultrastructure.¹⁶⁵ This ultimately can lead to endothelial cell swelling, extravasation of plasma protein and debris, release of proteolytic enzymes, congestion of alveoli with inflammatory cells, and massive interstitial pulmonary edema and altered gas exchange.

Factors that have not consistently proven beneficial in protecting the lungs during cardiac surgery include off-pump surgery,¹⁶⁶ steroids,¹⁶⁷ maintenance of mechanical ventilation during CPB,¹⁶⁰ and modifications of temperature management.¹⁶⁰ Heparin-coated circuits have been shown to improve lung compliance and pulmonary vascular resistance, with particular improvement seen when low heparin protocols are used.¹⁰⁶ Maintaining lung perfusion during CPB (Drew-Anderson technique) refers to using the patient's own lungs as an oxygenator and supplying only biventricular pump function; this may have some clinical benefits,¹⁶⁸ but its practicality is not universally accepted.

Renal Dysfunction

Data from the Multicenter Study of Perioperative Ischemia Research Group¹⁶⁹ demonstrated a 7.7% incidence of postoperative renal dysfunction after on-pump CABG, with 1.4% of all patients needing dialysis. Renal insufficiency is associated with increased hospital and ICU stay and mortality, emphasizing its clinical relevance. Although factors such as nonpulsatile flow and obstructive atheromatous microemboli may contribute, the diffuse inflammatory change related to CPB may have an independent toxic effect on the kidneys.

Numerous strategies have been advocated as potentially renal-protective during CPB. Leukodepletion has been shown in a prospective randomized controlled trial to decrease the need for continuous furosemide infusion and renal replacement therapy.¹⁷⁰ Mannitol is a popular diuretic agent that can increase diuresis if added in dosages of 10 to 30 g. This drug has also been shown to preserve creatinine levels and lower urinary albumin excretion rates after pediatric cardiac surgery.¹⁷¹ Renal-dosage dopamine (2 to 3 µg/kg/min) has been assessed in several randomized controlled trials of patients at high risk for renal failure, and the results have been controversial.¹⁷² Fenoldopam, a selective dopamine-1 receptor agonist, was shown in a randomized controlled trial to preserve renal function as demonstrated by a lower rate of acute kidney injury, particularly in those patients requiring inotropic support.¹⁷³ Other options that have shown promise in renal protection during heart surgery include avoidance of transfusions¹⁷⁴ and early initiation of statin therapy.¹⁷⁵ The use of off-pump techniques has not been definitively proven to decrease the incidence of renal insufficiency after heart surgery.¹⁶⁶

EXTRACORPOREAL TEMPORARY CARDIOPULMONARY SUPPORT

The ability to offer prolonged periods of external cardiopulmonary support became possible with the advent of

modified oxygenators that minimized blood trauma. This strategy is commonly referred to as extracorporeal membrane oxygenation (ECMO), and its first reported successful use involved posttraumatic ARDS.¹⁷⁶ The application was subsequently tested in a randomized controlled trial in 1979 in a larger ARDS cohort, but the survival results were equal or worse than in controls, possibly because of technical issues and bleeding complications.¹⁷⁷

On the other hand, in neonates it was proposed that the goals of ECMO in respiratory failure were different in that temporary support was only deemed necessary until persistent fetal circulation resolved. This hypothesis was born out by the first neonatal survival reported in 1975.¹⁷⁸ The strategy was subsequently strongly confirmed in trials in this population such that it became standard therapy. Currently the most common application worldwide of ECMO is in neonates with congenital diaphragmatic hernia.¹⁷⁹

Subsequent improvements in technology, experience, and cannulas provided the grounds for resurgence in interest in its use in adults, with more judicious early application. The CESAR trial provided the first strong support in terms of long-term survival to discharge from the ICU in adults with severe lung failure.¹⁸⁰ Cases worldwide are reported by participating organizations in a registry and the volume has been increasing steadily each year.¹⁷⁹ There was a particular upsurge in cases at the time of the H1N1 crisis, with reports of up to 70% survival in this desperately ill cohort, further solidifying the credibility of this strategy.¹⁷⁹

Indications and Options for Temporary Support

Mechanical means of lung support (exclusive of traditional endobronchial ventilation) can be applied for CO₂ removal and/or O₂ delivery. It can be used in short-term situations with reversible lung injury with the primary goal to remove CO₂ (respiratory dialysis), such as with exacerbations of COPD. Isolated lung support is also indicated in patients with severe potentially reversible respiratory failure when the predicted mortality with optimal medical therapy is expected to exceed 80%.¹⁸¹ Techniques do not treat the underlying lung condition; rather they improve gas exchange while enabling the institution of protective lung strategies to prevent further ventilator-mediated damage. Lung support can be used as a bridge to lung transplant in patients with irreversible lung injury and as a bridge to recovery post lung transplant. In many situations, respiratory failure is associated intimately with secondary cardiac failure and support is required for both systems, but treatment can be modified to lung-specific support as the hemodynamics stabilize.

Temporary mechanical cardiac support refers to mechanical strategies exclusive of ventricular assist devices (Table 63-1). It has been applied in situations of bridge to recovery (e.g., postcardiotomy shock, cardiogenic shock post resuscitation)¹⁸² as well as in transport of critically ill patients with portable devices.¹⁸³ It may also be the procedure of choice in "bridge to decision" in which there is severe shock with organ failure or an unknown neurologic status, whereby recovery must be

TABLE 63-1 Indications for Temporary Cardiopulmonary Mechanical Support

Pulmonary	Extracorporeal CO ₂ removal (reversible lung injury) Bridge to recovery (acute reversible lung injury) Bridge to transplant (irreversible lung injury)
Cardiac	Post lung transplant Bridge to recovery (e.g., post cardiectomy, cardiogenic shock) Bridge to decision Bridge to transplant
Both	Bridge to recovery Bridge to transplant

demonstrated before more definitive commitment with a long-term device is made.

Finally, in cases with severe pulmonary hypertension, combined organ support may be the targeted strategy. This may involve support until recovery if it is deemed the pulmonary pressures may improve or as a bridge to transplant such as with end-stage decompensated primary pulmonary hypertension.

Technical Factors

In the most common form of temporary support (venoarterial [VA]), a combination of venous outflow and arterial inflow is used. There are multiple options for venous inflow depending on the goals of therapy and the minimum required flow, including peripheral (e.g., femoral vein) and central (e.g., right atrial). Arterial outflow can also include peripheral or central (aortic). Peripheral femoral inflow in the absence of some degree of native ventilation to ensure oxygenation of aortic root blood may result in cardiac dysfunction. Femoral cannulation is also associated with a high risk of limb ischemia, but the leg can be perfused with a distally oriented cannula in the superficial femoral artery or in the dorsalis pedis artery.¹⁸⁴ Axillary return may allow for improved options for patient ambulation,¹⁸⁵ but it may be associated with hyperperfusion of the arm. Finally, in pediatric ECMO, the internal jugular vein and the internal carotid artery are used preferentially.

Venovenous (VV) ECMO is a novel strategy primarily used for isolated pulmonary support. In this scenario, blood is withdrawn from a distal venous site to undergo gas exchange, and the oxygenated blood is then returned in the region of the tricuspid valve continuing to the left circulation via the pulmonary bed. Originally this was accomplished with two carefully positioned catheters, but it may now be achieved with a double-lumen single-cannula (Fig. 63-14) Avalon catheter.

Centrifugal pumps are preferentially used for ECMO; however, in children, the use of the centrifugal pump during prolonged ECMO has been associated with increased hemolysis, hyperbilirubinemia, need for inotropic support, and renal failure as compared to roller pumps.¹⁸⁶

As a result of the use of biocompatible circuits and the absence of a cardiectomy, a lower ACT ($1.5 \times$ baseline)

FIGURE 63-14 Integrated dual-lumen catheter for venovenous extracorporeal membrane oxygenation.

may be employed with temporary support. Native ventilation is commonly used to varying degrees to prevent atelectasis, during partial support and during weaning. Management is reproducible in experienced teams, and nurses with advanced training can supervise patients independently in high-volume units. Support can be continued for weeks to months if necessary. Principles of care include daily monitoring for hemolysis, maintenance of normal hemoglobin, treatment of coagulopathy, permissive mild thrombocytopenia ($50,000\text{--}100,000 \times 10^9/\text{liter}$), and optimal flows ($50\text{--}100 \text{ mL/kg/min}$, titrated to $\text{SaO}_2 > 80\%$). Drugs must be carefully titrated because of impaired bioavailability of as much as 65% related to tubing circuit adsorption.¹⁸⁷

Currently with all forms of support, ventilator weaning should be considered, and long-term support of extubated patients may significantly decrease the risk of critical illness deconditioning.¹⁸⁸

Contraindications to the use of temporary cardiopulmonary support include irreversible neurologic injury, nonmanageable coagulopathy, and limited anticipated survival related to other issues (advanced malignancy, end-stage liver failure). Lung assist is contraindicated in the setting of high-pressure positive pressure ventilation more than 1 week. Relative contraindications include trauma, sepsis, pulmonary hemorrhage, and malignancy.

Complications of ECMO include systemic thromboembolism, limb ischemia, maldistribution of O_2 , increased left ventricular wall tension, and cannulation site bleeding. The latter must be addressed with compulsive cannula site exploration and correction of any coagulopathy.

Lung Assist

Whereas ECMO provides complete lung replacement, newer, less invasive technologies offer lung assist.¹⁸⁹ CO_2 removal and O_2 delivery can be considered separately and can use a combination of the ventilator and extracorporeal support to achieve these goals.

FIGURE 63-15 ■ Interventional lung assist (iLA Novalung, Hechingen, Germany) for extracorporeal CO₂ removal in severe respiratory failure. FA, Femoral artery; FV, femoral vein; MO, membrane oxygenator.

Lung assist devices are primarily effective for CO₂ removal (extracorporeal CO₂ removal [ECCOR]) using the native lung for oxygenation.¹⁹⁰ The interventional lung assist (iLA Novalung, Hechingen, Germany) consists of a low-resistance gas exchange device with a diffusion membrane of polymethylpentene fibers (Fig. 63-15). The design incorporates a complex flow pattern created with fiber weaving to maximize O₂ and CO₂ diffusion but primarily affecting CO₂ removal. With an inflow cannula from the femoral artery of one leg and outflow to the femoral vein of the other, flow is driven by the patient's pressure up to 2.5 liter/min. An external pump can be incorporated to increase flows up to 5.5 liter/min.

This device has been used as a bridge to recovery or lung transplantation in neonates and young children,¹⁹¹ in trauma,¹⁹² and influenza (H1N1).¹⁹³ The iLA has been used as a bridge with central cannulation between the pulmonary artery and the left atrium in decompensated patients with primary pulmonary hypertension awaiting transplant.¹⁹⁴ Limb ischemia remains the most common complication with this device.

Low-flow CO₂ removal devices have also been introduced for clinical use. The HemoLung device (Alung, Pittsburgh, PA) consists of heparin-coated siloxane dual-lumen venous catheters in femoral and jugular format, which can be used for respiratory dialysis. Flow through the integrated centrifugal pump is only 350 to 550 mL/min and the patients can be completely ambulatory. Other low-flow devices include the Hemodec (Salerno, Italy), the iLA active (Novalung, Hechingen, Germany), and the Decap system (Hemodec, Salerno, Italy).

THE FUTURE OF CARDIOPULMONARY BYPASS

There is great potential for continuing evolution of CPB circuit design and techniques that may enhance clinical outcomes with cardiac surgery. For example, newer devices have incorporated novel technology to integrate all CPB components to markedly minimize the pump prime and the surface area (mini-circuits). In a prospective randomized controlled trial with a preestablished transfusion protocol, these devices have been demonstrated to minimize the effect of hemodilution and platelet consumption, resulting in decreased blood loss and a significant decrease in the transfusion of red cells.¹⁹⁵ However, the universal application of mini-circuits will necessitate marked acceptance of modified surgical techniques (e.g., retrograde autologous priming, absence of venous reservoir or cardiectomy), which may limit their generalized acceptance and facility.

An illustrative paper by Bartels and coworkers¹⁹⁶ demonstrated our previous naiveté with regard to the means by which we conduct CPB. "On the basis of our scientific evaluation of the current literature on 48 principles of CPB, not a single condition was of sufficient scientific merit to conclude that we were dealing with a principle for which there is clear evidence, scientific agreement, or both, that a given procedure or treatment is useful and effective."¹⁹⁶ On the other hand, positive steps have now been taken to apply evidence-based guidelines to perfusion practice.⁸ It is only through this contemplation of our everyday actions in the operating room that we can hope to continue to minimize the effect of CPB on our patients.

Fixation

Vacuum-Assisted Closure Therapy

Treatment Algorithm

Most cardiac surgery procedures are performed through a median sternotomy, an approach pioneered by Milton in 1897.¹ Although fairly uncommon, infective complications for this type of incision remain a difficult challenge for cardiac surgeons.

DEFINITION

Sternal wound complications have been classified by El Oakley and Wright² as follows:

1. *Mediastinal dehiscence*: median sternotomy wound breakdown in the absence of clinical or microbiologic evidence of infection.
2. *Mediastinal wound infection*: clinical or microbiologic evidence of infected presternal tissue and sternal osteomyelitis, with or without mediastinal sepsis and with or without unstable sternum. Subtypes include *superficial wound infection*, wound infection confined to the subcutaneous tissue; and *deep wound infection (mediastinitis)*, wound infection associated with sternal osteomyelitis with or without infected retrosternal space.

It is the latter subtype that will be the focus of this chapter. According to the guidelines from the Centers for Disease Control and Prevention in the United States,³ deep sternal wound infection (DSWI) can be defined by one of the following: (1) the presence of an organism isolated from culture of mediastinal tissue or fluid; (2) evidence of mediastinitis seen during operation; (3) one of the following conditions: chest pain, sternal instability or fever ($>38^{\circ}\text{C}$) *in combination* with either purulent discharge from the mediastinum or an organism isolated from blood culture or culture of mediastinal drainage.

INCIDENCE AND CAUSES

The incidence of DSWI in most recent series ranges from 0.75% to 2.4%.⁴⁻⁷ In our institution, prospectively collected results for 23,499 sternotomies performed between 1992 and 2007 were retrospectively reviewed. A total of 267 patients presented with DSWI, accounting for 1.1% of the surgical population.⁸ *Staphylococcus aureus* and coagulase-negative staphylococci are the most commonly found microorganisms.⁹ In their review of 30,102 consecutive patients undergoing sternotomy for cardiac surgery between 1990 and 2003, Tang and collaborators found them to be respectively responsible for 42% and 24% of DSWI.¹⁰ Gram-negative bacteria and fungi are less commonly encountered. These offending organisms have been associated with different predisposing factors and modes of presentation.^{11,12} Coagulase-negative staphylococci colonize the wound from the normal skin flora and proliferate within a self-contained pocket protected by an extracellular polysaccharide biofilm. The infection is mostly seen in obese patients and those affected by chronic obstructive pulmonary disease (COPD), associated with a slow and late onset with resulting sternal instability but fewer systemic signs.

S. aureus infections are more aggressive in nature and more often associated with classic systemic signs and bacteremia. Perioperative contamination and nasopharyngeal colonization are important sources for this type of infection. Gram-negative bacteria are more commonly associated with a more complicated postoperative course, prolonged intensive care unit (ICU) stay, and concomitant nosocomial infections such as pneumonia, urinary tract infections, and abdominal sepsis, which were found in almost 25% of patients in our series.⁸

RISK FACTORS

Host predispositions and numerous perioperative environmental and technical aspects can play a significant role in the development of DSWI. There is a vast body of literature concerning the most important of these factors, commonly divided as preoperative, perioperative, and postoperative, which have been associated with a higher incidence of DSWI.^{4,5,13-25}

Obesity, diabetes mellitus, COPD, heart failure, renal failure, smoking, poor dental hygiene, older age, and male gender have consistently been identified in patients more prone to DSWI. Preoperative considerations also include prolonged hospital stay or the use of an intra-aortic balloon pump.

Untimely administration of antibioprophyllaxis,²⁶ poor management of hyperglycemia, use of both internal thoracic arteries (ITAs), redo surgeries, excessive use of bone wax, and prolonged procedural times have all been described as perioperative contributing factors, whereas postoperative reexploration for bleeding, transfusions, prolonged ICU stay, and prolonged intubation time are commonly associated with the postoperative period. Specific mechanisms have been proposed to account for the increased risk seen in patients affected by these conditions.

Poor distribution of antibiotics in adipose tissue and inadequate skin preparation in obese patients, impaired wound healing by elevated blood glucose in diabetes mellitus, improper sternal vascularization associated with the use of both ITAs, and heart failure-induced low cardiac output are common examples. In our series,⁸ prolonged intubation was the strongest predictor of DSWI with an odds ratio of 5.9, probably reflecting composite indices of risk and patient fragility. Bilateral internal mammary artery grafting was the second strongest predictor, with an odds ratio of 2.7 in the latest period.

DIAGNOSIS

DSWI diagnosis should be suspected whenever sternal tenderness or instability, erythema, fluid collection, wound dehiscence, or purulent discharge is found, especially in the presence of fever or leukocytosis. The diagnosis is essentially clinical and is based on the criteria listed in the previous "Definition" section. Blood cultures should be done when patients present with pyrexia, and identification of a staphylococcal bacteremia is almost pathognomonic. Any fluid discharge from the wound should also be cultured. Chest radiography has limited interest for diagnostic purposes but may reveal ruptured or malpositioned wires as well as sternal fractures or dehiscence as indirect signs of DSWI.²⁷ Computed tomography (CT) can help determine the extent, depth, and localization of the infectious process. It has been associated with 95.3% sensitivity and 81.7% specificity.²⁸ CT is also useful for guided needle aspiration and culture.

Nuclear imaging has not been used extensively, but leukocytes labeling with ^{99m}Tc-HMPAO has shown

promise as a reliable method for the early diagnosis of sternal infections in a small cohort of 41 patients.²⁹

We suggest that a transthoracic and/or transesophageal echocardiogram be performed in patients presenting with DSWI following a valvular replacement, to rule out the presence of a concomitant prosthetic endocarditis.

PREVENTION

Modifiable preoperative risk factors are intuitive targets for DSWI prevention. Smoking cessation and weight loss should be sought whenever possible. Perioperative strategies to reduce DSWI are numerous and individually described in this section; overall attention to these multiple details is of utmost importance. The incidence of nasal colonization with *S. aureus* ranges from 10% to 15% in the normal population and increases the risk of sternal wound infection.¹² Perioperative intranasal mupirocin application is a safe and inexpensive method to significantly reduce DSWI.³⁰⁻³² Skin preparation should be performed immediately before surgery, and hair should be removed preferably by clipping rather than by shaving.³

Prophylactic antibiotics prior to surgery are recommended and should be administered so that therapeutic concentrations can be reached before the initial incision and maintained throughout the procedure and for several hours following closure. The use of cefazolin 1 g or cefuroxime 1.5 g intravenously is recommended within 30 to 60 minutes preprocedure; vancomycin should be used, in a dose adjusted to renal function, for patients with a history of penicillin allergy or at risk for methicillin-resistant *S. aureus*.³ Unless there is evidence of ongoing sepsis, prophylactic use of antibiotics should not be extended beyond 36 to 48 hours.³³

Blood glucose levels should be controlled, because maintenance at or below 110 mg/dL has been shown to decrease morbidity and mortality among critically ill patients, regardless of a presurgical history of diabetes.³⁴ The efficacy of local antibiotic-eluting products remains controversial. Gentamicin-collagen sponges placed retrosternally before suture closure have been associated with reduction of DSWI in a controlled randomized study,³⁵ results that have been disputed in other trials.³⁶⁻³⁸ As stated in a meta-analysis by Mavros et al,³⁹ the statistical heterogeneity among existing studies underlines the need for additional large, high-quality randomized controlled trials.

Furnary and coworkers have demonstrated that maintenance of blood glucose between 150 and 200 mg/dL through continuous insulin infusion, compared with intermittent subcutaneous insulin, led to a significant reduction in the incidence of DSWI (0.8% vs. 2%).⁴⁰ During surgery, caution while performing a precise midline sternotomy and discriminate use of electrocautery and bone wax are simple ways to help prevent DSWI. The use of both ITAs should also be weighed against potential risks of infection and tailored for each patient. Diabetic patients are particularly at risk, especially when other factors such as obesity and COPD are present.⁴¹ There is growing evidence that skeletonized bilateral ITA

grafting can contribute to lowering the risk of DSWI in these patients.⁴²⁻⁴⁷

A closure technique that affords sternal stability should be adopted.⁴⁸ A sufficient number of sternal wires should be used, especially in high-risk patients.^{49,50} Newer sternal closure systems using titanium, nitinol, and cable-tie devices or based on sternal bone adhesive offer promising alternatives for optimal sternal fixation and have been associated with lower rates of sternal wound complications.⁵¹⁻⁵⁴ External systems used to reduce sternal instability, such as vests or corsets, can be useful adjuncts.^{55,56} A review of a variety of primary closure techniques designed to further stabilize the sternum and lower the risks of dehiscence and infection is proposed by Losanoff and coworkers.⁵⁷

SURGICAL MANAGEMENT

As for any surgical wound infection, DSWI management requires appropriate assessment of the underlying causes, including identification of the causing pathogens, and usually involves surgical revision, thorough débridement and wound preparation for reconstruction, with or without soft tissue flaps and/or plate fixation. Poststernotomy mediastinitis was initially approached by surgical revision with frequent dressing changes to promote granulation leading to sternal rewiring or secondary wound closure. The method was flawed by long hospital stays, secondary superinfection with fungi, hemorrhage, and mortality rates as high as 45%.⁵⁸

Primary Closure and Irrigation

An important contribution to the treatment of DSWI came in 1963 from Shumaker and Mandelbaum,⁵⁹ who first described the technique of débridement, sternal reclosure, and mediastinal antibiotic irrigation. The technique offers the advantages of a closed wound and a stable sternum but is associated with limitations in patient mobility and slower rehabilitation; high rates of failure are still being reported.⁶⁰ Nonetheless, this approach is still used and is a viable option.

Poncelet and coworkers⁷ proposed an algorithm including primary closure for most patients with DSWI. Multiple procedures, eventually including the use of muscle flaps, were necessary in more than a third of the patients, and the 90-day mortality rate for patients with DSWI remained high at 14.5%. Using multiperforated (Redon) catheters that are used for irrigation and progressively removed over the course of several days, another group reported an overall in-hospital mortality of 23.6%.⁶¹ These results contrast with those reported by Molina and coworkers,⁶² who have used a single approach for 24 years that consists of débridement, lateral reinforcement of the sternum, and the placement of a combination of irrigation catheters and suction tubes both anterior and posterior to the closed sternum. The skin is closed, the irrigation catheters are kept in place for 1 week, and then suction tubes progressively are taken out over 5 to 7 additional days. The authors report a 98% cure rate and no mortality in 114 patients. A more recent

retrospective analysis comparing the use of Redon drains and vacuum-assisted closure therapy (see [Vacuum-Assisted Closure Therapy](#), later) showed a reduction in hospital stay with no significant impact on mortality, which remained high in both groups (14.0% and 12.5%, respectively).⁶³

Soft Tissue Flaps

Omental Flaps

Based on the greater omentum's rich blood supply, immunologic properties and potential capacity to nourish infected tissue and improve wound healing, Lee and colleagues introduced the idea of omental flaps to treat DSWI in 1976.⁶⁴

Despite good flap viability and interesting protection afforded by the technique, with a reported 16% mortality in a cohort of 47 patients of whom more than 50% had methicillin-resistant *S. aureus* infection,⁶⁵ donor-site complications resulting from omental flap transposition remain high⁶⁶ and include abdominal wall herniation (20%), hematoma (8%), and seroma (4%). Omental flaps are now mostly used as an adjunct to other therapeutic modalities or as a second resort when previous techniques have failed, and it is thus difficult to fully appreciate the intrinsic benefits of the approach. A study⁶⁷ reviewing their use in 52 patients over a 15-year period demonstrated a 60-day mortality of 11% when used for primary reconstruction compared to 29% when used as a salvage procedure. Flap-related complications occurred in 23% of cases, with complete flap loss in 3.8%. Donor-site complications were seen in 27% of cases.

More recently, minimally invasive laparoscopic harvesting of the omentum has been proposed as an alternative to formal laparotomy.⁶⁸ This less invasive approach, associated with fewer abdominal complications, is increasingly used in our institution.

Pectoralis Major Muscular Flaps

Flaps derived from the pectoralis major are dependent on its primary and secondary blood supplies, respectively the thoracoacromial neurovascular bundle and the perforators from the ITAs.⁶⁹ Complete transposition by folding the muscle over on itself requires transection of the thoracoacromial artery and can obviously not be done on the side where an internal mammary artery has been harvested; however, partial flaps can be created by preserving the primary blood supply and advancing part of the muscles to cover the sternum. In most cases both muscles are prepared using this latter approach, detached from their insertions on the humeri and advanced into the wound, perfused by the thoracoacromial arteries. One of the muscles can also be folded using the secondary blood supply for the pedicle if the ipsilateral ITA is intact. This can allow for the splitting of the muscle along its midline, extending the surface that can be covered. In a review of 67 patients receiving 91 tissue flaps, Zahiri and coworkers found that overall complication rates were significantly higher after pectoralis major advancement (32.5%) versus turnover (3.7%) reconstruction.⁷⁰

When the entire sternum cannot be covered, concomitant use of the rectus abdominis is sometimes required. However, by skeletonizing the vascular pedicle back to near the origin of the thoracoacromial axis to create an extended island flap of the pectoralis major,^{71,72} the need for additional muscle flap preparation can be virtually eliminated.

In a review of their 20-year experience with mediastinitis management using pectoralis major flaps in 76.6% of their last 186 patients, Jones and coworkers reported a 9.1% mortality with 18.8% flap closure complications.⁷³

Rectus Abdominis Muscular Flaps

The rectus abdominis can be used as a muscular or myocutaneous vertical flap, using the superior epigastric artery and vein for blood supply, assuming integrity of the arteriovenous arcade connecting the inferior and superior epigastric vessels.⁶⁹ This approach is used mostly when pectoralis major flap transposition does not provide adequate coverage of the wound or has failed. Oh and coworkers⁷⁴ report 12% mortality with 29% flap complications in 34 patients operated over a 10-year period. Another report, from Jacobs and coworkers,⁷⁵ using at least one intercostal artery as additional blood supply to the superior gastric artery in 72 patients over 15 years, demonstrates 7% mortality and 7% morbidity. Retrospectively comparing the results of 41 patients and 56 patients, respectively undergoing pectoralis and rectus abdominis reconstruction, Davison and coworkers⁷⁶ showed similar success rates (defined as a healed wound and discharged patient at 30 days) of 85% and 86%, 34% morbidity for both approaches as well as 5% and 7% respective mortality rates. Rectus abdominis transposition proved more efficient at preventing dehiscence of the inferior third of the sternum, whereas an advantage was found for pectoralis transposition in preventing superior third complications.

Use of muscle flap for chest wall reconstruction is the subject of a comprehensive and recent review by Bakri and coworkers.⁷⁷

Fixation

Rigid titanium plates can be used for sternal edges apposition to promote bony union in complicated sternal closures. These plates are used mostly when there is sternal instability, which is usually seen in early presentations of DSWI. Plates are transversally placed across the sternal halves at separate levels (manubrium, second, third, and fourth ribs) (Fig. 64-1). Plate fixation was used in 50 such cases in conjunction with simple bilateral pectoralis advancement flaps for repair of sternal wound dehiscence, osteomyelitis, and nonunion after median sternotomy. Complete bony union was achieved in 98% of cases, with only 2% recurrences.⁷⁸ The technique has also been used in prophylaxis in 326 patients between 2000 and 2005, and results were compared to those of 215 patients with similar risk profiles treated with a standard approach.⁷⁹ Fixation plates were associated with a reduction in mediastinitis complications from 13% to none,

FIGURE 64-1 ■ Titanium fixation plates fixed with locking screws on the cartilaginous portions of the ribs.

and mortality from 8.6% to 3.8%. The benefits of plating appear to be maximal during the early postoperative period, but late sternal wound complications remain an issue. Both our group and Snyder and coworkers found a 10% recurrence rate after primary plating.^{80,81} Although the management of these patients requires rehospitalization and removal of osteosynthesis material, infections tend to be superficial and secondary treatment with vacuum-assisted closure is usually successful.

Vacuum-Assisted Closure Therapy

The use of vacuum-assisted closer (VAC) therapy for wound healing, a concept introduced by Morykwas in 1997,⁸² is based on the application of local negative pressure through an open-pore polyurethane foam covered with an adhesive drape and connected to a vacuum source (Fig. 64-2). Continuous drainage in an otherwise moist environment increases blood flow in the wound and favors cellular organization and granulation tissue formation while providing sternal stabilization to allow for physiotherapeutic mobilization of the patient.¹³ This technique can be used as a single-line treatment modality followed by reclosure, or as a temporary means of providing optimal conditions for second-line procedures such as flap transposition or plate fixation. It has been successfully applied by several groups^{13,19,83-89} and shown to shorten the length of hospital stays to improve survival in DSWI patients. Bleeding remains the most frequent complication associated with the use of VAC therapy, but this can be avoided by covering the right ventricle with paraffin gauze and performing débridements in the safe environment of a proper operating room.^{90,91}

Based on the demonstration that C-reactive protein levels can be used to guide the optimal timing for VAC cessation,⁹² an algorithm for treatment has been proposed by Sjögren and coworkers.¹³

Treatment Algorithm

A similar algorithm has been concomitantly developed in our institution starting in January 2002.⁸ Of 10,319

FIGURE 64-2 ■ Installation of the vacuum-assisted closure (VAC) system. **A**, Open-pore foam sponges used to fill the space between sternal halves. **B**, Complete system with adhesive drape and suction tubing connected to vacuum source.

patients undergoing cardiac surgery, 149 presented with DSWI (1.4%) during that period. Patients were systematically brought to the operating room for débridement, removal of all foreign material (including sternal wires), and wound culture at different levels. Appropriate antibiotherapy was instituted and a VAC system installed with negative pressure ranging from -75 mm Hg to -125 mm Hg. Wound care with additional débridement was performed as needed every 2 to 3 days, with return to the operating room when necessary, until the wound was clean, repeated cultures were negative, and C-reactive protein levels were below 60 mg/L. Thick paraffin gauzes were used under the foam sponges to protect the right ventricle. Most patients were then treated with bilateral pectoralis major muscle flap advancement without humeral detachment and titanium plate fixation (62%), while 22% had VAC therapy followed by pectoralis major transposition only, and 16% were closed by rewiring only. In comparison to the remaining 13,180 who were treated without VAC therapy as a first-line approach, in-hospital mortality was lowered from 14.1% to 4.8% ($P = 0.009$). After adjustment for risk factors, early survival at 1, 2, and 3 years was also better after VAC therapy (respectively 93% vs. 83%, 90% vs. 76%, and 88% vs. 61% at

FIGURE 64-3 ■ Adjusted survival for patients treated with multimodal therapy, including rewiring with or without pectoralis major flap advancement with or without plate fixation, either with (VAC) or without (No-VAC) preparation with vacuum-assisted closure therapy.

1, 2, and 3 years for the VAC vs. non-VAC groups, $P = 0.02$) (Fig. 64-3).

In our experience, more complex muscle flap transpositions, including laparoscopic omentopexy combined with pectoralis muscle flap wound coverage, have been limited to those cases in which bony union could not be achieved (e.g., following total sternectomy in cases of severe sternal osteomyelitis) and have been performed mostly for mediastinal protection purposes.

Deep sternal wound infection remains an important problem after median sternotomy, associated with significant morbidity and mortality rates. Good clinical practice based on appropriate preventive measures, early recognition, and treatment are mandatory because they have been shown to provide significant improvement in outcome.

MOLECULAR MANIPULATION

Despite meticulous adherence to presently known principles of myocardial protection, perioperative myocardial damage related to ischemia-reperfusion injury continues to occur after cardiac operations that have been performed in a technically adequate manner. Ischemia-reperfusion injury associated with surgically induced myocardial ischemia secondary to aortic cross-clamping results from the attenuation or cessation of coronary blood flow such that oxygen delivery to the myocardium is insufficient to meet basal myocardial requirements to preserve cellular membrane stability and viability. Recovery after surgically induced ischemic arrest involves (1) resumption of normal oxidative metabolism and the restoration of myocardial energy reserves; (2) reversal of ischemia-induced cell swelling, loss of ion gradients, and adenine nucleotide losses; and (3) repair of damaged cell organelles such as mitochondria and the sarcoplasmic reticulum.

HISTORICAL DEVELOPMENT

After the initiation of open heart surgery with use of extracorporeal circulation by Gibbon,¹ it soon became obvious that aortic cross-clamping was necessary to provide a bloodless field to facilitate the precise repair of intracardiac defects, to prevent air embolism when the left side of the heart was opened, and to avoid a turgid myocardium resistant to retraction. To overcome the difficulties of operating on a rheumatic mitral valve in a patient with aortic regurgitation, Melrose and colleagues² introduced the concept of “elective cardiac arrest” by rapidly injecting into the aortic root, after aortic cross-clamping, a 2.5% potassium citrate solution in warm blood to arrest the heart. Soon thereafter, experimental and clinical evidence³ demonstrated the development of severe myocardial necrosis associated with the Melrose technique.

During the 1960s, two distinct technical pathways for management of ischemic arrest evolved. The “rapid operators” performing uncomplicated cases with short ischemic times adopted the use of normothermic ischemic arrest, until operative mortalities from the “stone heart” syndrome related to ischemic contracture of the myocardium⁴ associated with low levels of high-energy phosphate moieties became apparent.⁵ Intermittent aortic cross-clamping, involving reperfusion of the coronary circulation for 5 minutes after 15 minutes of ischemic arrest, is an empirical technique, still in use, and was based on the concept that after 15 minutes of ischemia, a sufficient concentration of high-energy phosphate moieties remained in the myocardium to allow replenishment of myocardial stores during the reperfusion period.⁶ Later studies demonstrated that there was no functional or metabolic advantage to intermittent reperfusion for normothermic ischemic periods up to 60 minutes.^{7,8} Nevertheless, intermittent cross-clamping accompanied by ventricular fibrillation continues to be used for coronary artery bypass surgery with results comparable to those of cardioplegic techniques.⁹

Fibrillatory Arrest

Electrically induced ventricular fibrillation with coronary perfusion was introduced by Glenn and Sewell¹⁰ and Senning¹¹ as a means of avoiding air embolism. However, Buckberg and Hottenrott¹² and Hottenrott and coworkers¹³ demonstrated subendocardial ischemia and necrosis with this technique, particularly in the hypertrophied ventricle. Later studies showed that if ventricular distention is avoided and coronary perfusion is maintained, postischemic fibrillation is not deleterious in the nonhypertrophied heart.¹⁴ Further validation of this technique, modified by mild hypothermia and the avoidance of aortic cross-clamping, has produced comparable clinical results for coronary revascularization.^{15,16}

Continuous Coronary Perfusion

In an attempt to mimic the physiologic state, continuous coronary perfusion with a beating heart at normothermia or mild hypothermia at 32°C to prevent the onset of ventricular fibrillation became the preferred technique of myocardial preservation in the late 1960s and early 1970s, particularly after the report by McGoon and colleagues¹⁷ of 100 consecutive aortic valve replacements with no deaths. When aortic valve regurgitation was present or aortic root surgery was performed, the heart was kept beating by perfusing the individual coronary arteries with cannulas inserted into the ostia. However, continuous perfusion became intermittent as coronary perfusion was often discontinued to achieve better visualization of the operative field during critical portions of the procedure.¹⁸ In addition, problems with the coronary cannula, such as poor fixation, leaking associated with calcified ostia, early division of the left main coronary artery resulting in high perfusion pressure necrosis, and damage to the coronary artery such as dissection and late stenosis, continued to occur.^{19,20} Nevertheless, the technique of continuous coronary artery perfusion, either during the performance

of complex aortic root surgery or for special situations, such as re-do mitral valve surgery through a right thoracotomy incision after previous coronary artery revascularization with arterial conduits, continues to be used.²¹

Hypothermia

The earliest attempts to perform open heart surgery before the advent of the heart-lung machine used systemic hypothermia produced by surface cooling not only to protect the heart but to protect the brain and other organs during circulatory arrest.^{22,23} Hypothermia protects the ischemic myocardium by decreasing heart rate, slows the rate of high-energy phosphate degradation,²⁴ and decreases myocardial oxygen consumption (Fig. 65-1).^{25,26} However, uniform cardiac hypothermia is difficult to achieve solely by the introduction of cold intracoronary perfusates, and systemic hypothermia is necessary, particularly in the presence of coronary obstruction, ventricular hypertrophy, rewarming of the right ventricle by the liver's acting as a “heat sink,” and environmental rewarming.²⁷ In an attempt to overcome this problem, Shumway and associates²⁸ introduced the concept of profound local (topical) hypothermia by filling the pericardial sac with ice-cold saline.²⁹ Although this technique is still used as an adjunct to other methods of myocardial protection, it is rarely used as the sole protective method because of the problem of warm bronchial collateral flow reaching the heart cavity, resulting in transmural temperature gradients and resultant ischemia.^{30,31}

Reintroduction of Cardioplegia

Whereas cardioplegia had been abandoned for alternative techniques in the United States after the adverse experience with the Melrose potassium solution, in Germany, Bretschneider³² continued studying induced cardiac arrest with use of a histidine protein buffer, sodium-poor, calcium-free, procaine-containing solution (Bretschneider solution). Clinical application soon followed,

FIGURE 65-1 ■ Relationship between body temperature and oxygen consumption in dogs cooled by means of an extracorporeal pump (mean value for 10 dogs). (From Gordon AS, Meyer BW, Jones JC: Open heart surgery during deep hypothermia without an oxygenator. *J Thorac Cardiovasc Surg* 40:787–812, 1960.)

with Kirsch and associates³³ using a magnesium aspartate–procaine solution. Hearse and coworkers³⁴ introduced the concept of using an extracellular rather than an intracellular solution (St. Thomas' solution), which was first applied clinically by Braimbridge and coworkers.¹⁸ On the basis of improved clinical outcomes, North American investigators^{35–38} initiated experimental studies using potassium cardioplegia followed by clinical reports^{39,40} demonstrating the efficacy of cardioplegia. During the next 3 decades, numerous investigators have continued their “quest for ideal myocardial protection.”^{41–44}

BIOLOGY OF SURGICALLY INDUCED MYOCARDIAL ISCHEMIA

Global ischemia is not an all-or-nothing phenomenon; rather, it is heterogeneous in that at any moment of time, myocardial cells will have varying extents of damage.^{45,46} These changes affect cellular metabolism, ion transport, electrical activity, contractile function, vascular responsiveness, tissue ultrastructure, changes in nuclear and mitochondrial DNA, release of free radical oxygen species, and activation of inflammatory components.⁴⁷

Myocardial Oxygen Consumption

Because the heart is an obligate aerobic organ, it depends on a continuous supply of oxygen to maintain normal function. Myocardial oxygen reserve is exhausted within 8 seconds after the onset of normothermic global ischemia.⁴⁸ Myocardial oxygen consumption (MVO_2) is compartmentalized into the oxygen needed for external work of contraction (80% to 90%) and the unloaded contraction, such as basal metabolism, excitation-contraction coupling, and heat production.^{49,50}

A unique aspect of myocardial energetics is that 75% of the coronary arterial oxygen presented to the myocardium is extracted during a single passage through the heart; thus, depressed coronary venous oxygen content persists despite a wide range of cardiac workloads. Therefore, the heart is susceptible to the limitations of oxygen delivery, whereby an increase in MVO_2 can be met only by augmentation of coronary blood flow. This is diametrically opposite to skeletal muscle, in which increased oxygen demand can initially be met by an increase in oxygen extraction. Clinically, a marked increase in coronary blood flow is observed at the beginning of the reperfusion period, after the aortic clamp is removed.

Biochemical Alterations

Under aerobic conditions, the heart derives its energy primarily from mitochondrial oxidative processes, using substrates such as glucose, free fatty acids, lactate, pyruvate, acetate, ketone bodies, and amino acids.^{51,52} However, oxidation of fatty acids provides the major source of energy production and is used in preference to carbohydrates.⁵³

As tissue PO_2 falls, oxidative phosphorylation, electron transport, and mitochondrial adenosine triphosphate

(ATP) production cease. Early in ischemia, the heart depends on the energy production of glycogenolysis and aerobic glycolysis (Pasteur effect). However, unlike other organs, the heart requires a minimum threshold of ATP to prevent irreversible ischemic contracture.⁵⁴ Reduced mitochondrial activity leads to the accumulation of glycolytic intermediaries, reduced NADH, and the reduction of pyruvate to lactate. The resultant severe intracellular acidosis impairs contractile function, enzyme transport, and cell membrane integrity. This results in a cellular loss of potassium and pathologic accumulation of sodium, calcium, and water (Fig. 65-2).⁵⁵

Ischemia-Reperfusion Injury

Ischemia-reperfusion injury occurs as the result of attenuation or cessation of coronary blood flow such that oxygen delivery to the myocardium is insufficient to meet basal myocardial oxygen requirements to preserve cellular membrane stability and viability. The initiation of myocardial injury requires an ischemic episode that, by itself, may induce reversible or irreversible cellular injury.^{56,57}

Reversible ischemia-reperfusion injury may be manifested as either stunning or hibernation. Stunning “describes the mechanical dysfunction that persists after reperfusion despite the absence of myocellular damage and despite the return of normal or near-normal perfusion.”^{58,59} A second form of reversible ischemia-reperfusion injury is hibernation, which is a syndrome of reversible, chronically reduced contractile function as a result of one or more recurrent episodes of acute or persistent ischemia, referred to as chronic stunning.

As in stunning, hibernating myocardium is viable but not functional and is reversible with coronary revascularization.^{60,61} There is good clinical evidence that despite seemingly adequate application of modern methods of myocardial protection, all patients undergoing cardiac surgery have varying degrees of myocardial stunning.^{62,63} Evidence to support this concept is based on the requirement of inotropic support for separation from bypass for hours or days after surgery in some patients who are eventually weaned from these drugs as the stunning abates, without objective evidence of a myocardial infarction.⁶⁴

Two major theories have been proposed as possible mechanisms leading to ischemia-reperfusion injury (Fig. 65-3). The calcium hypothesis suggests that the inability of the myocyte to modulate intracellular and intraorganellar calcium homeostasis induces a cascade of events culminating in cell injury and death (Fig. 65-4). Ischemia leads to the induction of metabolic acidosis and the activation of the sodium-proton exchanger, resulting in the transport of hydrogen ions to the extracellular space and the movement of sodium into the cytosol. As the sodium-calcium exchanger is activated, sodium is transported to the extracellular space and calcium is taken up into the cytosol, increasing cytosolic calcium concentration ($[Ca^{2+}]_i$). Increased $[Ca^{2+}]_i$ accumulation is also augmented by ischemia-induced depolarization of the membrane potential, which allows the opening of the L-type calcium channels and further calcium entry into the myocyte.

FIGURE 65-2 ■ The biochemical anatomy of the normal functioning myocardial cell. The three main reactions using ATP are (1) myosin ATPase involved in the development of wall tension, (2) Ca^{2+} , Mg^{2+} -ATPase involved in sequestration of Ca^{2+} that enters the cell with each beat and the Ca^{2+} that is liberated from sarcoplasmic reticulum in the activation of contractile protein, and (3) Na^{+} , K^{+} -ATPase involved in Na^{+} efflux. The action of this vectorial ATPase establishes the monovalent cation gradient across the membrane that is used to maintain cell excitability and the efflux of Ca^{2+} . (From Feinberg H, Levitsky S: *Biochemical rationale of cardioplegia*. In Engelman RM, Levitsky S, editors: *A textbook of clinical cardioplegia*, New York, 1982, Futura, pp 131–139.)

FIGURE 65-3 ■ Mechanisms of ischemia-reperfusion injury. Putative mechanisms of the calcium and free radical hypotheses and inflammation in the generation of ischemia-reperfusion injury. ROS, Reactive oxygen species.

FIGURE 65-4 ■ Sources of calcium regulation. The inability of the myocyte to modulate intracellular and intraorganellar calcium homeostasis during ischemia and during early reperfusion is the basis of the calcium hypothesis for ischemia-reperfusion injury. Increased intracellular calcium ($[Ca^{2+}]_i$) induces a cascade of events culminating in increased mitochondrial and nuclear calcium accumulation and cell injury and death.

Cellular and cytosolic calcium-dependent phospholipases and proteases are in turn activated, inducing membrane injury and the further entry of calcium into the cell. These processes alter myocardial cellular homeostasis, leading to cellular dysfunction or, if they are of sufficient duration or intensity, cell injury or death. Alternative explanations include the concept of reperfusion-induced myocardial contracture resulting from rapid re-energization of contractile cells with persistent calcium overload affecting myofibrillar calcium sensitivity.⁶⁵

The free radical hypothesis suggests that the accumulation of partially reduced molecular oxygen, collectively known as reactive oxygen species, during the early stages of reperfusion causes myocardial cellular damage and cell death through microsomal peroxidation of the cellular phospholipid layer, leading to loss of cellular integrity and function (Fig. 65-5).⁶⁶ The generation of reactive oxygen species is believed to be mediated by xanthine oxidase, activation of neutrophils, or dysfunction of the mitochondrial electron transport chain. It has been suggested that the generation of reactive oxygen species may induce cellular membrane damage, thus facilitating calcium entry and the induction of cellular death. This hypothesis unifies both prevailing theories and is currently considered to be valid. However, therapeutic attempts to control calcium and reactive oxygen species overload have not yielded meaningful advantage.⁶⁷

Alternative explanations include the concept of lethal reperfusion injury, defined as death of myocardial cells that were viable immediately before reperfusion.⁶⁸ In an excellent review by Yellon and Hausenloy,⁶⁹ alternative cardioprotective strategies are suggested to manage this injury by reperfusion injury salvage kinase pathways and targeting mitochondrial permeability transition pores to avoid mitochondrial calcium overload. Cyclosporine, a

FIGURE 65-5 ■ Sources of reactive oxygen species generation. The free radical hypothesis suggests that accumulation of partially reduced molecular oxygen, collectively known as reactive oxygen species (ROS), during the early stages of reperfusion causes myocardial cellular damage and cell death. Reactive oxygen species are formed by the acquisition of a single electron, making them highly reactive and cytotoxic. The major reactive oxygen species in order of production are superoxide (O_2^-), hydrogen peroxide (H_2O_2), hydroxy radical ($\cdot OH$), and lipid peroxides. ROS formation has been shown to cause myocellular injury through microsomal peroxidation of the cellular phospholipid layer, leading to loss of cellular integrity and function.

potent inhibitor of mitochondrial permeability transition pores, has recently been shown to limit infarct size after percutaneous coronary intervention during acute myocardial infarction.⁷⁰

Irreversible Cell Injury

Irreversible cell injury, described ultrastructurally by Schaper and coworkers,⁴⁶ occurs by two morphologically distinct pathways, necrosis and apoptosis. Necrosis is initiated by noncellular mechanisms with cell swelling, depletion of ATP stores, and disruption of the cellular membrane involving fluid and electrolyte alterations.⁷¹ In contrast, apoptosis (programmed cell death)⁷² is an evolution-based mode of cell death characterized by a discrete set of biochemical and morphologic events involving the regulated action of catabolic enzymes (proteases and nucleases) that results in the ordered disassembly of the cell, distinct from cell death provoked by external injury.^{73,74}

Inflammation

Inflammation has been implicated as a secondary mechanism contributing to injury after reperfusion. It is initiated through complement activation leading to the sequential formation of a membrane attack complex, which creates a cellular lesion and eventual cell lysis.⁷⁵ In addition, cytokines, vasoactive and chemotactic agents, adhesive molecule expression, and leukocyte and platelet activation participate in the inflammatory process, producing cytotoxic molecules that facilitate cell death.^{76,77} Oxygen-derived free radical scavengers have also been used to limit reperfusion injury.⁷⁸ Tissue factor, an inflammatory and procoagulant mediator, initiates the extrinsic coagulation cascade, resulting in thrombin generation and fibrin deposition, and may be related to the no-reflow phenomenon.⁷⁹ Clinical applicability of anti-inflammatory agents awaits well-designed clinical trials because studies up until now have not shown any “meaningful cardioprotective effect.”^{69,80,81}

In addition, endothelium-dependent microvascular responses and coronary artery spasm may be related to reduced myocardial perfusion after reperfusion.⁸²

Effects of Age

The vulnerability of the heart to ischemia-reperfusion injury is altered with temporal development. The newborn heart is more resistant to the effects of ischemia-reperfusion, which may be related to developmental differences in calcium transport and sequestration, and it is better able to restore myocardial function and myocardial high-energy phosphate stores after an ischemic event.⁸³⁻⁸⁵ Others have postulated that, in the neonate, during ischemia, anaerobic glycolysis is the only metabolic pathway that can produce high-energy phosphates.⁸⁶

In the adult heart, functional recovery is significantly delayed, and the recovery of high-energy phosphate stores is slower in returning to preischemic levels.⁸⁷ As the heart ages, there are anatomic, mechanical, ultrastructural, and biochemical alterations that compromise

the adaptive response of the heart.⁸⁸ As a result, the senescent myocardium is less tolerant than the mature myocardium to surgically induced ischemia.⁸⁹ The susceptibility of the aged myocardium to ischemia-induced injury is evident at many levels. Morphologically, with age, left ventricular mass is increased and the size of the left ventricular cavity is reduced, accompanied by increased calcification of the valve annulus and coronary arteries.⁹⁰ Ultrastructurally, there is decreased mitochondria-to-myofibril ratio, cardiac myocyte enlargement, and loss of mitochondrial organization as well as alteration in myocardial contractile properties.⁹¹ As a consequence of these changes, cardiac surgical operative mortality increases with age.⁹²

Cyanosis

Cyanosis significantly increases the vulnerability of the myocardium to ischemia-reperfusion injury.^{93,94} However, cyanotic myocardial cells exhibit normal metabolism when they are provided with adequate oxygen and substrate.⁹⁵ Mortality rates in patients undergoing elective repair for tetralogy of Fallot are related to the method of myocardial protection as well as to the patient's age, duration and extent of cyanosis, and extent of hypertrophy.⁹⁶

Ventricular Hypertrophy

Increased myocardial mass is an adaptive response to prolonged increases in myocardial workload as a result of pressure or volume overload. If it is untreated, progressive ventricular hypertrophy results in ventricular dilation and contractile dysfunction.⁹⁷ Hypertrophied hearts have an increased vulnerability to ischemic injury, which has been attributed to accelerated loss of high-energy phosphate moieties,⁹⁸ increased accumulation of lactate and hydrogen ions, earlier onset of ischemic contracture, and accelerated calcium overload after reperfusion.^{87,99,100} With ventricular hypertrophy, epicardial coronary arteries dilate in response to increased oxygen demands, and decreased capillary density and vascular dilation reserve in the subendocardial regions result in increased ischemic vulnerability.¹⁰¹ Subendocardial ischemia leading to necrosis can occur during periods of hypotension, inadequate cardiopulmonary bypass, and ventricular fibrillation.¹⁰² The hypertrophied heart is particularly susceptible to ischemic injury in the early postoperative period, when hypotension associated with surgically induced myocardial stunning, hypothermia, and vasoconstrictor agents are present.¹⁰³

CARDIOPLEGIA: BASIC PRINCIPLES

A rational approach for protecting the heart during surgically induced ischemia not only must focus on the requirements for sustaining the ischemic cell but also must be compatible with the technical aspects of the operative procedure. Operative procedures require a flaccid arrested heart, a bloodless operative field, and sufficient time for the satisfactory repair of complex cardiac defects. Moreover, the ability of the heart to

assume normal electromechanical function adequate to support the systemic circulation must rapidly follow the ischemic interval. The need for inotropic support or mechanical support devices (e.g., intra-aortic balloon assist device, ventricular assist device) to wean the patient from cardiopulmonary bypass when support was not required preoperatively represents a failure of myocardial protection. Studies demonstrate that dopamine treatment of postischemic myocardial stunning induces apoptosis.¹⁰⁴ Nevertheless, despite meticulous adherence to known principles of myocardial protection, these events not infrequently and randomly occur and represent the limitations of present knowledge. Most investigators agree that the basic principles for adequate myocardial protection include (1) rapid induction of arrest, (2) mild or moderate hypothermia, (3) appropriate buffering of the cardioplegic solution, (4) avoidance of myocardial edema, and (5) avoidance of substrate depletion.¹⁰⁵⁻¹⁰⁷

Rapid Cardiac Arrest

Rapid cardiac arrest remains the mainstay of adequate myocardial protection and is “achieved by targeting various points in the excitation-contraction coupling pathway” (Fig. 65-6).¹⁰⁸ The induction of immediate cardiac arrest after the aorta has been clamped minimizes the depletion of high-energy phosphate moieties by useless mechanical work (Table 65-1). Potassium is the most common agent used for chemical cardioplegia and produces rapid diastolic arrest (Fig. 65-7). As the extracellular potassium concentration increases, the resting myocardial cell membrane becomes depolarized; the voltage-dependent fast sodium channel is inactivated, arresting the heart in diastole; and the slow calcium channel is activated, resulting in cytosolic calcium overload.^{109,110} The optimum concentration of potassium is thought to vary between 15 and 40 mmol/liter,¹¹¹ although

it has been suggested that concentrations exceeding 20 mmol/liter promote calcium overload and subsequent injury.¹¹² Because the heart will remain arrested until the concentration of extracellular potassium or other cardioplegic ingredient is decreased by noncoronary collateral mediastinal blood flow, reinfusions of cardioplegia are necessary every 15 to 30 minutes.¹¹³ Clinical studies indicate that despite the infusion of large volumes of hyperkalemic cardioplegic solution for complex procedures requiring prolonged ischemic times, serum potassium levels in patients with normal renal function rarely exceed 5.5 mEq/liter, because increased urinary excretion of potassium rapidly compensates for the endogenous administration of potassium.¹¹⁴

Agents inducing polarized arrest, in which the cell membrane potential remains close to resting potential, have significant advantages by limiting ionic movement and thereby reducing myocardial energy use.¹⁰⁸ Sodium channel blockade, which arrests the heart by preventing the rapid sodium-induced depolarization of the action potential, includes procaine¹¹⁵ and tetrodotoxin.¹¹⁶ This class of drugs has been used successfully experimentally but is rarely used clinically at present. Potassium channel openers induce arrest by membrane hyperpolarization, couple the membrane potential to the cellular metabolic status, and afford cardioprotection by a similar mechanism associated with ischemic preconditioning.¹¹⁷ Two potassium-adenosine triphosphate (K_{ATP}) channel subtypes have been shown to coexist in the myocardium; one subtype is located in the sarcolemma (sarc K_{ATP}) membrane and the other in the inner membrane of the mitochondria (mito K_{ATP}), and they can be pharmacologically manipulated by openers and blockers.^{106,118,119}

Potassium channel openers have been used in conjunction with hyperkalemic and magnesium-containing cardioplegic solutions, although their clinical use remains controversial.^{120,121} However, mitochondria-specific

potassium channel openers, such as diazoxide, have been demonstrated to have potential benefits when they are used with magnesium-supplemented potassium cardioplegia.^{122,123}

Adenosine is an endogenous nucleoside formed as a consequence of the breakdown of high-energy phosphate and is rapidly phosphorylated by adenosine kinase to adenosine monophosphate and incorporated into the high-energy phosphorus pool or deaminated by adenosine deaminase, present in erythrocytes, to inosine, which is transported from the cell.¹²⁴ Extracellular adenosine is cleared through cellular uptake, primarily by erythrocytes and vascular endothelial cells, and has a reported half-life of less than 10 seconds in whole blood, which limits its use during a prolonged period of surgically induced ischemia.¹²⁵ Adenosine induces hyperpolarized cardiac arrest by antagonizing calcium channels and has been shown to inhibit both the sinoatrial and the atrioventricular nodes and atrial myocardial contraction.¹²⁶ Adenosine, by its ability to antagonize the direct depressant effects on both the sinoatrial and atrioventricular nodes and atrial tissue, results in sinus slowing and arrest. Clinically, adenosine has been used as a pretreatment before the initiation of cardiopulmonary bypass, when it has been shown to increase postoperative cardiac index and to reduce creatine kinase release¹²⁷; as an arresting agent by bolus infusion¹²⁸; and as an additive to potassium cardioplegia, when it reduces the time to arrest¹²⁹ and reduces potassium-induced cytosolic calcium overload.¹³⁰ It may also improve functional recovery when it is infused

during the reperfusion period.¹³¹ Compared with the acellular St. Thomas cardioplegic solution, the addition of adenosine appeared to enhance postoperative cardiac function in a series of patients undergoing coronary revascularization.¹³² Phase II studies suggest that adenosine may reduce postoperative complications,¹³³ although the results are open to question.¹³⁴ Nevertheless, additional clinical trials are suggested.¹³⁵

Hypothermia

Hypothermia, whether it is mild (tepid at the room temperature range of 28°C to 32°C) or moderate (22°C to 25°C), continues to remain an indispensable adjunct for adequate myocardial protection. As noted earlier (see [Historical Development](#)), hypothermia decreases the rate of the metabolic degradation of energy stores during surgically induced ischemia. In addition, experimental evidence shows a significant decrease of left ventricular MVO_2 of the heart in the beating nonworking, fibrillating, and arrested states at 22°C compared with a myocardial temperature of 37°C (Fig. 65-8).¹³⁶ However, there is minimal advantage in reducing the myocardial temperature below 22°C, because the MVO_2 is decreased by only a minimal amount, from 0.31 mL at 22°C to 0.27 mL at 15°C per 100 g of left ventricular tissue per minute.¹³⁷ Moreover, in the clinical setting, it is virtually impossible to maintain a uniform myocardial temperature below 22°C solely by the use of cold (4°C) intracoronary cardioplegia infusates accompanied by

FIGURE 65-8 ■ Effects of hypothermia on myocardial oxygen consumption in the potassium-arrested dog heart. (From Chitwood WR, Sink JD, Hill RC, et al: The effects of hypothermia on myocardial oxygen consumption and transmural coronary blood flow in the potassium-arrested heart. *Ann Surg* 190:106–116, 1979.)

regional hypothermia, particularly in the presence of coronary obstructions, ventricular hypertrophy, and variations in mediastinal noncoronary collateral blood flow. In addition, the atrial and ventricular septa are warmed by systemic and pulmonary venous return, heat sinks such as the liver warm the base of the heart, and the anterior-situated right ventricle is warmed by the operative environment. Because of the lack of uniformity of myocardial temperatures in various myocardial segments, there is no correlation between myocardial tissue acidosis and temperature, leading to the recent abandonment by many surgeons of routine myocardial temperature monitoring during operative procedures.^{138,139}

Buffering of the Cardioplegic Solution

Buffering of the cardioplegic solution is necessary to combat the unremitting intracellular acidosis associated with surgically induced myocardial ischemia. Because the myocardium has the highest oxygen use of any organ in the body related to its concentration of mitochondria, ischemia results in the rapid accumulation of hydrogen ions and the reduction of intracellular pH, which has been quantified by the measurement of tissue PCO₂ and hydrogen ion with phosphorus P 31 nuclear magnetic resonance spectroscopy in the laboratory and a pH probe in the operating room.^{87,140} With the recent development of a myocardial tissue pH probe, there is clinical evidence that maintenance of the tissue pH of 6.8 or greater is associated with adequate myocardial protection (Fig. 65-9).¹⁴¹ Thus, frequent infusions of cardioplegia, every 15 to 20 minutes, are necessary to prevent intracellular

acidosis from reaching irreversible metabolic levels. In addition, hypothermia assists in the neutralization of acidosis because pH rises 0.0134 unit for each decrease in degree centigrade.¹⁴² However, the infusion of hypothermic cardioplegia does not restore pH_i to prearrest levels but rather prevents further deterioration of the pH. When intermittent warm blood cardioplegia is used, lengthening of the ischemic period progressively increases intracellular metabolic acidosis and is probably associated with increased injury during repeated episodes of normothermic arrest.^{143,144} Bicarbonate, phosphate, aminosulfonic acid, tris(hydroxymethyl)aminomethane (THAM), and histidine buffers have all been used as cardioplegia additives to modulate pH.

Avoidance of Myocardial Edema

Avoidance of myocardial edema by controlling osmolarity is important to control volume regulation of the fluid compartments of the heart because myocardial edema is a known consequence of ischemia.¹⁴⁵ The extent of myocardial edema has been shown to be directly modulated by osmolarity and onconicity of cardioplegia, with decreases being directly associated with increased myocardial edema and impaired diastolic filling.¹⁴⁶ Hypotonic cardioplegic solutions cause myocardial edema¹⁴⁷; hyperosmotic cardioplegia with an osmolarity in excess of 400 mOsm/liter has been shown to cause myocardial dehydration.¹⁴⁸ Isotonic solutions in the range of 290 to 330 mOsm/liter or slightly hyperosmolar solutions appear to have the greatest clinical use, which is of particular importance in dealing with acellular cardioplegic solutions.⁴⁰ Inert sugars including mannitol and sorbitol as well as metabolizable sugars such as glucose and dextrose have been used to increase osmolarity. However, when large volumes of continuous cardioplegia are administered, there is concern about producing hyperglycemia. Oncotic agents such as albumin and macromolecules, including dextrans and hydroxyethyl starches, have been used to prevent myocardial edema.¹⁴⁹ In addition to cardioplegic infusions, the hemodilution from crystalloid priming of the extracorporeal circuit, the activation of humoral and cellular mediators that increase microvascular permeability, and the impairment of myocardial lymphatic function may play major roles in the development of myocardial edema. Myocardial lymphatic function is dependent on the beating heart to transport fluid and is significantly reduced or completely stopped during cardiac arrest. Experimental evidence has indicated that during normothermic continuous antegrade blood cardioplegia, myocardial lymph flow is reduced to less than 20% of that in the normal beating heart.¹⁵⁰

ALTERNATIVE ARRESTING AGENTS AND ADDITIVES

Beta Blockers

As the ascending aorta is clamped, the non-exocytotic release of norepinephrine from the cardiac sympathetic nerves acts on β-adrenergic receptors on the outer surface

FIGURE 65-9 ■ pH and myocardial protection. pH (37°C) tracing in the left ventricular wall in a 67-year-old man undergoing complex aortic valve replacement. Measurements were obtained from three sites: anterior left ventricular (LV) wall, posterior LV wall, and anterior right ventricular (RV) wall. pH_{37C} reached a low of 6.0 in the posterior LV wall and 5.8 in the RV wall. This marked discrepancy between anterior and posterior wall pH_{37C} occurred in the face of continuous delivery of blood cardioplegia at high rates, mostly through the coronary sinus. Delivery of cardioplegic solutions through the ostium of the left main (LM) alone, through the coronary sinus alone, or simultaneously through the LM and coronary sinus failed to reverse the fall in pH_{37C} in the posterior LV and anterior RV walls. Integrated mean pH_{37C} during the period of aortic clamping was 7.30 in the anterior LV wall, 6.2 in the posterior LV wall, and 6.05 in the anterior RV wall, indicating poor protection of the posterior LV wall and anterior RV wall. The patient had to be defibrillated three times and required significant inotropic support to be weaned from cardiopulmonary bypass (CPB). He continued to require inotropic support for 24 hours postoperatively. CP, Cardioplegia; XC, cross-clamping. (From Khuri SF, Josa M, Marston W, et al: First report of intramyocardial pH in man: II. Assessment of adequacy of myocardial preservation. *J Thorac Cardiovasc Surg* 86:667–678, 1983.)

of the sarcolemma, causing an increase in cAMP-dependent protein kinase activity, phosphorylation of the calcium release channels, and increased Ca²⁺ influx, resulting in increased Ca²⁺-dependent contractility and rapid depletion of glycogen stores.¹⁵¹ Early studies suggested that long-acting beta blockers improved myocardial protection during ischemia but unfortunately have a prolonged negative inotropic effect, which limits their clinical use.¹⁵² For the most part, beta blockers such as propranolol have been used as an adjunct to anesthesia to block β-adrenergic-stimulating episodes associated with coronary ischemia during the course of the operative procedure. Ultra-short-acting cardioselective beta blockers such as landiolol and esmolol provide polarized cardiac arrest by maintaining the membrane potential at or near the resting membrane potential.¹⁵³ The cardioselectivity of these agents is 50 to 250 times that of propranolol, and the half-life of esmolol is only 9 minutes because it is rapidly hydrolyzed by red blood cell esterase.¹⁵⁴ Esmolol has been used to enhance myocardial protection during intermittent arrest¹⁵⁵ and has been shown to provide myocardial preservation equivalent to or better than cold crystalloid or blood cardioplegia.^{156–158} With esmolol cardioplegia, there is a slow undulating ventricular contraction that may decrease myocardial edema but does not provide a quiescent operating field.

Adenosine-lidocaine (adenocaine) cardioplegia provides an exciting alternative to depolarizing cardioplegia.¹⁵⁹ Adenosine-lidocaine cardioplegia has been shown to provide a shorter time to electromechanical arrest, greater postischemic recoveries of aortic flow, a lower coronary vascular resistance during infusion, and greater MVO₂ as compared to St. Thomas' Hospital solution, while maintaining the myocardial cell membrane potential at its resting state.¹⁶⁰

Agents Affecting Calcium Transport

The infusion of calcium-free cardioplegic solutions induces rapid diastolic cardiac arrest by inhibiting excitation-coupling and increases permeability of the sarcolemma.¹⁶¹ When a calcium-containing perfusate is then reinfused, during reperfusion, there is a rapid influx of calcium into the cell, resulting in myocardial contracture and extensive ultrastructural damage, the "calcium paradox."^{162,163} Nevertheless, hypocalcemic cardioplegic solutions have been used during hypothermic arrest to prevent ischemic contracture and necrosis.¹⁶⁴ Calcium antagonist agents administered before ischemia have been proposed as a possible mechanism to reduce ischemic cellular injury. Calcium channel blocking agents, including verapamil, diltiazem, and nifedipine, prevent

calcium-induced calcium release in myocardial cells and, as an adjunct to normothermic cardioplegia, have been shown to improve postischemic systolic function.¹⁶⁵ Calcium blockers have no effect if they are administered before reperfusion, are temperature dependent, and have limited effect during hypothermia. Because high concentrations are required for cardioprotection, their prolonged membrane binding prevents rapid recovery, thus limiting their clinical usefulness.

Magnesium inhibits calcium entry into the cell by displacing calcium from its binding sites in the sarcolemmal membrane.^{166,167} It has limited use as an arresting agent because high concentrations are required, cardiac arrest is delayed, and postischemic functional recovery is decreased in comparison to potassium cardioplegia.² The advantages of magnesium have been shown to be optimal when it is included with high-potassium cardioplegia, in which it has been demonstrated to ameliorate cytosolic, nuclear, and mitochondrial calcium accumulation; preserve high-energy phosphate moieties; and enhance postischemic functional recovery.^{168,169}

Avoidance of Substrate Depletion

Metabolic substrates have been added to cardioplegic solutions to enhance anaerobic metabolism during ischemia or to provide citric acid cycle intermediaries to facilitate homeostasis during reperfusion. Agents used include glucose and insulin^{170,171}; nucleosides,¹⁷² such as adenosine,¹⁷³ aspartate, and glutamate¹⁷⁴; and L-arginine to stimulate nitric oxide production.¹⁷⁵ Although metabolic substrate enhancement has been used in various clinical situations, none has achieved universal adoption.

CRYSTALLOID (ACELLULAR) AND BLOOD CARDIOPLEGIA

Crystalloid Cardioplegia

With the advent of myocardial protection, asanguineous solutions composed of varying electrolyte compositions, but always featuring hyperkalemic diastolic arrest, were clinically used in Europe^{17,30,32} in the early 1970s and in the United States^{38,39} in the late 1970s. However, these solutions contained minimal amounts (0.6 mL/100 mL at a PO₂ of 100 mm Hg at a temperature of 10°C) of dissolved oxygen, whereas the myocardium consumes 0.33 mL of oxygen per 100 g at 15°C. Because even a short period of ischemia results in the gradual accumulation of oxygen debt, moderate to severe myocardial hypothermia is necessary to prevent the rapid degradation of energy stores (Fig. 65-10).^{38,176} To overcome the oxygen deficit issue, oxygenation of crystalloid cardioplegia has been clinically used and has demonstrated a decrease in creatine kinase MB levels in patients when the cross-clamping time exceeded 29 minutes compared with a group of patients who received unoxygenated cardioplegia.¹⁷⁷ Nevertheless, subsequent clinical studies with unoxygenated crystalloid documented significant decreases in rates of operative mortality and perioperative myocardial infarction

FIGURE 65-10 ■ High-energy phosphates. Adenosine triphosphate (ATP) values during aortic cross-clamping (60 min) and reperfusion (30 min) for control (no treatment), intermittent reperfusion (15-min cross-clamping and 5-min reperfusion), regional hypothermia, and potassium (KCl) cardioplegia. (From Wright RN, Levitsky S, Rao KS, et al: Potassium cardioplegia: an alternate method of myocardial protection. *Arch Surg* 113:976-980, 1978.)

for coronary artery surgery, as demonstrated by the large Collaborative Study in Coronary Artery Surgery.¹⁷⁸ For the most part, most groups at that time, including our own, used Ringer solution (sodium chloride, 147.3 mmol/liter; potassium, 4.02 mmol/liter; and calcium chloride, 2.25 mmol/liter) to which was added 24 mmol/liter of potassium chloride to effect a total dose of 28 mmol/liter, 7 g/liter of glucose, and 0.8 mL of THAM.¹⁷⁹ The resultant solution had an osmolarity of 375 mOsmol/liter and a pH of 7.42 at 37°C. The classic St. Thomas' solution differed by having a lower concentration of potassium chloride, 19.59 mmol/liter, and added 15.90 mmol/liter of magnesium chloride and 1 mmol/liter of procaine hydrochloride.¹⁸

Clinical steps for myocardial protection with use of crystalloid cardioplegia include the following.

1. Before the onset of surgery, the operating room temperature is cooled to 63°F to 65°F (17°C to 19°C) to avoid warming of the anterior surface of the heart by convection and radiation from high-intensity lighting.
2. Cardiopulmonary bypass is initiated at a temperature of 28°C. A cannula is placed in the ascending aorta proximal to the aortic root for the antegrade infusion of cardioplegic solution and for the removal of air after the clamp is removed from the ascending aorta and as the patient is weaned from bypass.
3. A myocardial electrocardiographic lead and temperature probe are placed on the anterior wall of the right ventricle because it constitutes two thirds of the anterior surface of the heart, and its rewarming during surgically induced ischemia may partially explain the occasional observation of selective right ventricular failure after the termination of bypass.¹⁸⁰ In addition, an insulation pad is placed in the posterior pericardial sac and along the left ventricular lateral wall to protect the left phrenic nerve

from thermal injury associated with regional hypothermia and to prevent rewarming of the heart from heat sinks (i.e., liver).

4. The systemic perfusate temperature is temporarily decreased to 10°C to 15°C to “precool” the heart (infusion hypothermia), and iced saline slush is placed into the pericardial sac to achieve rapid myocardial cooling. Transient periods of ventricular fibrillation during this period of initial cooling appear to have no adverse effects.
5. When a myocardial temperature of 28°C is reached, the ascending aorta is cross-clamped and cold crystalloid cardioplegia solution at a temperature of 5°C is infused into the aortic root at a pressure not exceeding 90 mm Hg. The initial volume has been empirically determined to be 10 mL/kg body weight. The myocardial temperature rapidly decreases to 10°C to 15°C, and asystole usually occurs within 10 to 15 seconds.
6. At the termination of the initial cardioplegic infusion, the systemic temperature is elevated to 20°C, and the systemic perfusion flow rate is decreased from 2.2 to 1.5 liter/min/m². In this manner, the collateral aortocoronary and bronchopulmonary blood flow is kept cold, and the lowered systemic perfusion pressure prevents rapid dilution and washout of the cardioplegic solution. Every 15 to 20 minutes, or earlier if there is an increase in myocardial temperature above 20°C or if there is any electrocardiographic activity or observed ventricular motion, the solution is reinfused at a volume of 5 mL/kg.
7. Five minutes before removal of the aortic clamp, the systemic perfusate temperature is raised to 30°C, and flow is increased to 2.2 liter/min/m². After the aortic cross-clamp is removed, the perfusate temperature is raised to 38°C and the room temperature is raised to 25°C to 30°C. Cardiopulmonary bypass is continued until the esophageal temperature is 37°C and the rectal temperature is in the range of 35°C to 37°C. Rewarming is usually necessary in the early postoperative period.

The major disadvantage of this technique is the extensive rewarming period, which may exceed 30 to 45 minutes. Nevertheless, this prolonged period on bypass allows the restabilization of metabolic inequities and the subsequent smooth weaning from bypass. Evidence includes clinical reports of the safe use of crystalloid cardioplegia for periods exceeding 150 minutes.¹⁸¹ However, clinical studies evaluating myocardial metabolism and ventricular function indicate that cold crystalloid cardioplegia results in slow recovery of myocardial metabolism and a poor response to postoperative hemodynamic stress.¹⁸² Although most surgeons in the United States have switched to blood cardioplegia techniques, many groups throughout the world continue to use crystalloid cardioplegia and to obtain excellent outcomes.

Blood Cardioplegia

In an attempt to avoid the oxygen deficits associated with crystalloid cardioplegia, blood was introduced as a

suitable vehicle to obtain optimum oxygenation.^{183,184} Alternative methods of increasing oxygenation, including oxygenated crystalloid,¹⁷⁷ fluorocarbons,⁷⁶ and stroma-free hemoglobin,¹⁸⁵ have never achieved significant clinical use. Moreover, experimentally, blood cardioplegia has been demonstrated to be superior to oxygenated crystalloid cardioplegia (Fig. 65-11).⁴⁸ In addition to the enhanced ability to exchange oxygen and carbon dioxide, the physiologic advantages of blood include the buffering and reducing capacity, the presence of colloid to avoid adverse oncotic pressure gradients, and the presence of oxygen free radical scavengers.¹⁸⁶ In addition, blood and albumin-containing crystalloid cardioplegia solutions have been shown to preserve microvascular responses compared with crystalloid cardioplegia.¹⁸⁷ However, concerns associated with cold blood cardioplegia include (1) the hypothermic shift to the left of the oxyhemoglobin dissociation curve, thereby reducing the release of oxygen at the tissue level; (2) the experimental evidence that blood cardioplegia may not protect the myocardium at low temperatures¹⁸⁸; and (3) the potential of hypothermia-induced sludging and red cell rouleau formation. Other studies have demonstrated that hypothermia at 5°C to 10°C does not affect capillary flow¹⁸⁹ and that the viscosity of blood is not significantly affected by hypothermia unless the hematocrit is greater than 50%,¹⁹⁰ which would be unlikely because during bypass, hemodilution maintains the hematocrit in the 20% to 25% range. Numerous experimental and clinical studies have advocated the superiority of either crystalloid or blood cardioplegia, without arriving at a definitive conclusion.¹⁹¹⁻¹⁹⁵

The ratio of blood to crystalloid in formulating the blood cardioplegic solution has undergone progressive change since the initial clinical introduction of this technique. The early blood cardioplegia solutions used a ratio of four parts blood to one part crystalloid (4:1) as hemodiluted blood was withdrawn from the perfusion circuit and mixed with a crystalloid solution containing citrate-phosphate-dextrose to lower ionic calcium, THAM for buffering, and potassium adjusted to produce a concentration of 20 to 30 mmol/liter to induce diastolic arrest. Experimental studies demonstrated that a hematocrit as low as 9% provided sufficient oxygen transport at hypothermic levels of 5°C to 10°C (Fig. 65-12).¹⁹⁶⁻¹⁹⁸ To avoid excessive hemodilution associated with administration of large volumes of cardioplegia solution, leading to dilutional coagulopathy, the blood-to-crystalloid ratio has been gradually increased from 4:1 to 8:1. This change has also been accompanied by increased use of tepid and warm cardioplegic techniques; the associated higher temperatures require a higher hematocrit to achieve oxygen transport to support myocardial metabolism. Miniplegia, or whole blood cardioplegia using minimal amounts of potassium and magnesium to achieve arrest, avoids the problem of hemodilution, eliminates concerns about buffering, and avoids pharmaceutical costs.¹⁹⁹ Although experimental studies have not shown any significant advantage in reperfusion myocardial edema in comparing miniplegia with 4:1 blood cardioplegia, the comparative hematocrits of 12% ± 2% and 7% ± 1%, respectively, used in this study are not in the clinical range of 22% to 25% for miniplegia, which may have adversely affected

FIGURE 65-11 ■ Myocardial oxygen consumption and stroke work. Energetic plots of myocardial oxygen consumption versus stroke work before (preischemia) and after (postischemia) unoxxygenated crystalloid cardioplegia, oxygenated crystalloid cardioplegia, and blood cardioplegia. Postischemic myocardial oxygen consumption versus stroke work relationships were significantly increased with both unoxxygenated crystalloid cardioplegia and oxygenated crystalloid cardioplegia arrest; in blood cardioplegia, the preischemia and postischemia myocardial oxygen consumption versus stroke work relationships were superimposable. LV, Left ventricle. (From Krukenkamp IB, Silverman NA, Levitsky S: The effect of cardioplegic oxygenation on the correlation between linearized Frank-Starling relationship and myocardial energetics in the ejecting postischemic heart. *Circulation* 76[5 Pt 2]:V122-V128, 1987.)

the results.²⁰⁰ However, in a clinical study comparing miniplegia with standard 4:1 blood cardioplegia, there was significantly greater $\dot{M}V\text{O}_2$, lower lactate release, and better postoperative left ventricular function in the miniplegia group.²⁰¹ Others have demonstrated decreased

FIGURE 65-12 ■ Oxygen use and hematocrit concentration. The increased postischemic oxygen use for maximally unloaded contraction (E_0) can be prevented by having a critical red cell mass in cardioplegic solution. This salutary effect of red blood cells cannot be accounted for solely by their oxygen-carrying capacity, as oxxygenated crystalloid and plasma solutions did not have similar efficacy. BCP, Blood cardioplegia with hematocrit of 9% and 17% volume; CCP, crystalloid cardioplegia; LV, left ventricle; ns, not significantly different; O_2CCP , oxxygenated crystalloid cardioplegia. (From Silverman NA, Del Nido P, Krukenkamp I, et al: Biologic rationale for formulation of antegrade cardioplegic solutions. In Chitwood WR, editor: *Cardiac surgery: state of the art reviews*, Philadelphia, 1988, Hanley & Belfus, pp 181-195.)

postoperative inotropic use with miniplegia compared with 4:1 blood cardioplegia, suggesting a decrease in postoperative stunning.²⁰²

Del Nido cardioplegia techniques used with neonates relies on the concept that anaerobic glycolysis produces high-energy phosphates during ischemia. The cardioplegia solution is administered as a single dose, using dilute blood in a 1:4 ratio, and uses histidine as a proton buffer, glucose as a substrate, low sodium and calcium concentrations and lidocaine for depolarization to limit sodium influx by blocking the window current.^{203,204} Recent studies suggest that del Nido solution may also be useful in the senescent heart.²⁰⁵

Methodologies

Cardioplegia Temperature. The debate regarding the appropriate cardioplegia temperature has shifted from the classic cold (5°C to 10°C) to warm (37°C) in the recent past and to tepid (28°C to 32°C) at present. Warm heart surgery assumes that aerobic arrest, whereby the heart is electromechanically arrested and continuously perfused with warm blood cardioplegia, is the ideal state for the performance of safe cardiac surgery.^{206,207} The apparent advantages of this technique include the presumed elimination of anaerobic ischemic injury with cross-clamp times safely extended up to 6.5 hours²⁰⁸; the early resumption of a normal sinus rhythm after removal of the aortic clamp; the avoidance of a prolonged rewarming and reperfusion time, thus decreasing total bypass time; and the elimination of systemic hypothermia and associated vasoconstriction in the early postoperative period. However, difficulties in visualization of the operative field, particularly in performing distal coronary anastomoses, mandated temporary discontinuation of the

warm cardioplegic infusion, resulting in ischemic injury if the ischemia time exceeded 15 minutes.¹⁴⁴ Additional problems include (1) ischemic injury when antegrade warm blood cardioplegia cannot be delivered homogeneously in the presence of aortic insufficiency and left main coronary ostial stenosis,²⁰⁹ (2) difficulties in maintaining complete electromechanical arrest, (3) the need for vasoconstrictive alpha agonists during bypass to maintain adequate perfusion pressure because of severe systemic vasodilation,²¹⁰ and (4) the risk of neurologic events related to cardiopulmonary bypass and associated microemboli, which is exacerbated if the brain is not cooled.²¹¹ Nevertheless, warm heart surgery offered the promise to resuscitate ischemically jeopardized myocardium during the course of the operative procedure.²¹² In addition, late results of the Warm Heart Trial demonstrated that late survival at 6 years was not significantly greater in the warm cardioplegia patients compared with the cold cardioplegia group and was significantly reduced in the group with nonfatal perioperative events.²¹³

Tepid (29°C) cardioplegia was introduced as a means of overcoming the deficits of warm cardioplegia, without the adverse effects of cold cardioplegia. In a series of clinical studies, Hayashida and coworkers²¹⁴ demonstrated that reducing the cardioplegia temperature from 37°C to 29°C did not alter MVO_2 , reduced anaerobic lactate and acid release during arrest, and preserved myocardial function. Further postoperative cardiac function enhancement was obtained with a combination of intermittent antegrade and continuous retrograde tepid cardioplegia.²¹⁵ In a series of low-risk patients undergoing coronary artery bypass, no difference in cardiac troponin release was found when comparing warm and tepid cardioplegia.²¹⁶

Delivery Systems. Numerous clinical studies have documented the efficacy of various cardioplegia delivery systems and perfusion intervals. All of these reports suffer from the variability in disease (e.g., extent of ischemic or fibrotic myocardium and the variation in segmental coronary disease) as well as the lack of prospective head-to-head comparisons of large numbers of patients. All of these issues contribute to the wide variety of empirical clinical choices. Antegrade administration of cardioplegia, by use of a catheter or needle, in the ascending aorta has been the initial, traditional approach. Difficulties include (1) rupture of an atherosclerotic plaque at the insertion site, resulting in either microemboli or aortic dissection; (2) aortic insufficiency, resulting in ventricular dilation and inadequate flow into the coronary arteries; (3) left main ostial, occlusive, and variable coronary artery obstructions, leading to cardioplegic maldistribution; and (4) enlargement of the catheter-induced aortic opening at the insertion site, particularly in association with a thin-walled aorta related to poststenotic aortic dilation.

Retrograde perfusion of the coronary sinus, initially described by Pratt,²¹⁷ was first used clinically by Lillehei and colleagues²¹⁸ during the early days of open heart surgery to protect the heart during aortic valve replacement. Interest was renewed with this technique after Menasché and associates²¹⁹ reported improved outcomes for aortic valve replacement, prompting numerous studies

on the anatomy and physiology of the coronary sinus.²²⁰ Although most clinicians use direct cannulation of the coronary sinus with a balloon-tipped catheter, Fabiani and coworkers,²²¹ in a series of clinical studies, suggested infusion into the pressurized right atrium (obtained by occluding the vena cava and main pulmonary artery) to impede shunting of the cardioplegic solution into the right atrium through the thebesian veins.

Major advantages of retrograde perfusion include (1) distribution of the cardioplegic solution to myocardial segments perfused by obstructed or occluded coronary arteries or the internal mammary artery during re-do coronary surgery; (2) avoidance of the need for direct coronary ostial cannulation, with its attendant traumatic injury and subsequent stenotic potential, in performing aortic root procedures; (3) ability to administer cardioplegia during mitral valve surgery without removal of the retractor; (4) ability to provide continuous cardioplegia; and (5) avoidance of debris and subsequent embolization from atheromatous vein graft material during re-do coronary surgery.

Problems associated with retrograde cardioplegia include (1) slowness in achieving diastolic arrest if it is used for the initial introduction of cardioplegia, (2) occasional difficulty in blind insertion of the catheter into the coronary sinus, (3) easy dislocation of the catheter into the right atrium despite the use of ribbed balloon-tipped catheters, (4) traumatic injury and perforation during insertion of the catheter and occasionally spontaneous rupture of the great cardiac vein in fragile older patients even with autoinflatable balloon-tipped catheters, and (5) inadequate perfusion of the right ventricle and posterior ventricular septum (Fig. 65-13).^{222,223} Major technical issues include the requirement to measure coronary sinus pressure constantly to avoid infusion pressures exceeding 30 mm Hg and never to exceed an infusion rate greater than 200 mL/min because venovenous anastomoses and shunts at higher flows will direct more than 60% of the potential "nutrient flow" into the ventricular cavities through the thebesian channels.^{224,225}

Descriptions of the simultaneous delivery of cardioplegia have been confused by variations in the definition

FIGURE 65-13 ■ Warm retrograde cardioplegia distribution. Percentage microsphere recovery according to anatomic site. Data are presented as the mean $\pm$ the standard error of the mean. The asterisk (*) denotes $P < 0.01$ versus the anterior left ventricle (post hoc Tukey test). (From Calderone CA, Krukenkamp IB, Misare BD, et al: Perfusion deficits with retrograde warm cardioplegia. *Ann Thorac Surg* 57:403–406, 1994.)

of the methodology. Most authors have avoided delivery of cardioplegia solution simultaneously into the coronary sinus and the aortic root to avoid excessive pressurization with subsequent injury to the coronary microvasculature and to allow rapid egress of the solution.²²⁶ Delivery of cardioplegia through the coronary sinus (retrograde) and concurrently antegrade through each completed vein graft by use of a manifold with multiple side arms and a single pump head, in association with venting of the aortic root, has been designated *combination delivery*.²²⁷ This technique has been especially useful after completion of all the distal anastomoses during coronary revascularization as the proximal anastomoses are being performed or during closure of the left atrium or aortotomy during valve surgery, and if it is performed at 37°C for approximately 20 minutes, it is essentially the first stage of reperfusion and allows the restoration of postischemic oxygen uptake to return to baseline levels.²²⁸ For the most part, most surgeons use all of these techniques, termed *integrated cardioplegia*, which involves antegrade, retrograde, and combination delivery systems in either a continuous or alternate manner, depending on the clinical circumstances.

Warm induction with warm oxygenated cardioplegia has been suggested as a means of achieving “active resuscitation” in energy-depleted hearts, before proceeding with maintenance cardioplegia by any means or temperature level.²²⁹ Whether 5 minutes is sufficient time to reverse the adverse biochemical effects of depleted high-energy phosphate stores remains open to question, although functional experimental studies demonstrate improvement.²³⁰

Terminal warm blood cardioplegia (“hot shot”) for 3 to 5 minutes before aortic unclamping has been experimentally and clinically demonstrated to improve post-bypass ventricular performance after cold maintenance blood cardioplegia.^{231,232} However, a controlled trial of terminal warm cardioplegia for 5 minutes versus simple reperfusion did not demonstrate any advantage.²³³ As with warm induction, the question of whether 3 to 5 minutes of warm blood reperfusion is sufficient to restore energy stores is open to question. To overcome this deficit, combination blood cardioplegia delivery may be the preferred approach with a better chance of restoring energy stores. On occasion, prolonged terminal warm cardioplegia may lead to intracellular potassium accumulation with resultant reperfusion asystole during the early reperfusion period and requires temporary ventricular pacing to wean the patient from bypass.²³⁴ Secondary cardioplegia, which involves rearresting the heart for a prolonged period (more than 20 minutes) of warm cardioplegia, is an extension of the concept of terminal warm cardioplegia and may be useful in patients difficult to wean from bypass or with uncontrolled arrhythmias.^{235,236}

Clinical steps for myocardial protection with use of blood cardioplegia include the following.

1. Hypothermia at the initiation of cardiopulmonary bypass is avoided, and both the perfusate and the cardioplegia temperature are allowed to equilibrate with room temperature (tepid, at approximately 29°C).
2. As the ascending aorta is cross-clamped, whole blood (miniplegia) antegrade cardioplegia is infused into the aortic root at a rate of 100 to 200 mL/min at an aortic root pressure of 90 mm Hg. A potassium concentration of 28 to 30 mmol/liter is initially used until diastolic arrest occurs, and then the potassium concentration is gradually dialed down until the lowest concentration (usually 3 to 5 mmol/liter) that will maintain arrest is achieved. After 5 mL/kg is administered antegrade, an additional 5 mL/kg is administered retrograde.
3. The occluded or most severely stenosed coronary vessel is bypassed first.
4. After each vessel is bypassed, cardioplegia, 5 mL/kg, is infused simultaneously down the conduits in an antegrade direction and the retrograde cannula by use of a single pump head with a multiport manifold.
5. After completion of the last bypass graft, systemic perfusate and cardioplegia rewarming is initiated. The proximal bypass grafts are inserted on the ascending aorta as blood is aspirated from the aorta to maintain a level of blood just below the opening in the aorta to avoid obscuring the operative field.
6. As the last proximal anastomosis is completed, potassium is discontinued in the retrograde infusion, and whole blood is infused to wash out potassium. Air is evacuated from the aorta and ventricles as the heart starts to contract, and the clamp is removed from the aorta.
7. After hemostasis is confirmed, cardiopulmonary bypass is discontinued. If the heart remains in asystole, temporary atrial and ventricular pacing is instituted.

PRE-, POST-, AND REMOTE CONDITIONING

Ischemic Preconditioning

Ischemic preconditioning (IPC), first described by Murry and coworkers,²³⁷ is an adaptive response of endogenous myocardial protection, in which the imposition of one or more brief periods of sublethal ischemia (3 to 5 minutes) followed by reperfusion protects the heart such that injury manifested by infarct size, apoptosis, and reperfusion-associated arrhythmias is significantly reduced during a subsequent period of sustained ischemia.²³⁸ Numerous studies have indicated that IPC, in a species-dependent manner, is associated with the preservation of creatine phosphate, ATP, and intracellular pH; decreased ultrastructural abnormalities; induction of heat-shock proteins; increased release of adenosine and activation of the adenosine receptors; activation of G proteins; and activation of protein kinase C.²³⁹ The effects of ischemic IPC are bimodal, occurring in two phases: an early phase and a delayed late phase or “second window” of cardioprotection. In the early phase, the protective effects of IPC are transitory, with infarct limitation being lost if the subsequent sustained ischemic insult is delayed beyond 30 to 120 minutes.²⁴⁰ Approximately 24 to 96

hours after the induction of IPC, a second window of less potent cardioprotection occurs in which the infarct protection is reestablished.^{241,242}

Collateral evidence exists to suggest that IPC may occur in patients undergoing balloon angioplasty²⁴³ or may be elicited by the trauma associated with the onset of cardiopulmonary bypass.²⁴⁴ Yellon and coworkers²⁴⁵ have shown that in patients on cardiopulmonary bypass, the use of IPC (two 3-minute periods of ischemia and 2 minutes of reperfusion) before 10 minutes of ischemia significantly preserved ATP measured during the initial reperfusion period. Additional studies also reported that the use of IPC in coronary artery bypass graft surgery significantly decreased troponin T levels at 72 hours compared with cold crystalloid St. Thomas' cardioplegia solution; no comparison with conventional blood cardioplegia was performed.²⁴⁶ Others have reported that either IPC provided no benefit compared with cold blood cardioplegia, because cardiopulmonary bypass per se induces preconditioning,^{244,247} or its use was deleterious in human cardiac surgery.^{248,249}

The use of IPC in off-pump coronary artery bypass grafting also is controversial. Laurikka and colleagues,²⁵⁰ in a randomized, controlled study, induced IPC by occluding the left anterior descending coronary artery with a silicon tape placed proximal to and distal to the site of the anastomosis for two cycles of 2 minutes of occlusion and 3 minutes of reperfusion; the IPC group had a significantly increased recovery of the mean stroke volume index with a significant decrease in mean heart rate on the first postoperative day and a significantly lower cardiac troponin I level compared with controls. Others²⁵¹ using similar protocols found no statistically significant differences between the IPC and control groups.

Remote ischemic preconditioning (RIPC), defined as transient ischemia and reperfusion in a tissue or organ remote from the heart (e.g., the extremities), has been demonstrated to protect the heart after surgically induced myocardial ischemia in both children and adults by decreasing postoperative serum troponin T release^{252,253} by protecting mitochondrial integrity.²⁵⁴ The mechanisms through which RIPC provides cardioprotection are believed to involve possible neural and humoral pathways or systemic responses that interact with known IPC effectors.²⁵⁵ In a large ($N = 332$) clinical study using peak 24-hour troponin I level as the primary outcome measure, Carrasco-Chinchilla et al²⁵⁶ reported no differences between remote preconditioning and control groups and reported that it was harmful in diabetic patients. However, in a well-controlled randomized clinical trial, others²⁵⁷ demonstrated RIPC reduced perioperative myocardial injury as measured by cardiac troponin I, increased survival, and lowered cardiac and cerebrovascular events. Additionally, a meta-analysis of 19 randomized trials involving 1235 patients undergoing cardiac surgery, demonstrated decreased cardiac troponin I levels in patients subjected to RIPC.²⁵⁸

Postconditioning

The induction of postconditioning occurs during the initiation of reperfusion rather than before index sublethal

ischemia, thus improving clinical usefulness.^{259,260} Various algorithms involving different reperfusion-ischemia and reperfusion times and sublethal index ischemia and reperfusion times have been formulated. The postconditioning algorithm consists of repeated ischemia and reperfusion episodes, resulting in an interrupted or stuttering reperfusion that ameliorates the effects of reperfusion injury.²⁶¹ The efficacy of postconditioning in a clinical setting has not met with as much success as in animal models and more study has been suggested to allow for clinical efficacy.²⁶² In human studies using percutaneous coronary intervention for acute ST-segment elevation myocardial infarction, postconditioning has been shown to be efficacious in reducing myocardial cell injury.^{263,264}

There is also controversy about the use of IPC in female patients and older adults. Previous studies have shown that young women have a greater resistance to myocardial ischemic injury and that this resistance is lost after menopause.^{265,266} Others have shown in the rodent model that IPC is less effective in the female than in the male.²⁶⁷ These differences are the result of differences in hormonal mediation of threshold stimulation, and the stimulus for IPC may need to be prolonged (i.e., prolonged initiating ischemic event) to achieve cardioprotection similar to that in males.²⁶⁸ In older adult hearts, IPC is less effective in ameliorating myocardial injury than in the mature heart.^{266,269}

SODIUM-HYDROGEN EXCHANGERS

Sodium-hydrogen exchangers (NHEs) play a central role in the regulation of intracellular sodium and calcium concentrations, pH homeostasis, and volume regulation by facilitating the electroneutral exchange of intracellular hydrogen ions for extracellular sodium ions across the cell membrane.²⁷⁰ Under basal conditions, the sodium-calcium exchanger extrudes calcium to maintain normal intracellular calcium concentration. However, during ischemia, intracellular sodium accumulates because of inactivation of the ATP-dependent sodium extrusion system. NHE-mediated sodium influx during ischemia reduces activity of the sodium-calcium exchanger, resulting in a net increase in intracellular calcium, which is exacerbated during reperfusion. Consequently, inhibition of the isoform NHE-1, located on the plasma membrane of the cardiac myocyte, is thought to inhibit calcium overload and to serve as a myoprotective agent.²⁷¹ The NHE isoforms can be nonspecifically inhibited by various antagonists, including amiloride and its 5-amino-substituted analogs as well as the benzoylguanidine derivative cariporide (HOE-642). The use of cariporide has been shown to reduce myocardial infarct size and to improve postischemic functional recovery after ischemia and reperfusion.²⁷² The administration of NHE-1 antagonists before ischemia or both before ischemia and during reperfusion has been shown to provide significantly greater cardioprotection compared with administration during reperfusion alone.^{273,274} Clinical trials in patients treated for an acute myocardial infarction by coronary angioplasty with cardiac enzyme release as a biological endpoint have resulted in conflicting results.^{275,276} In an

additional randomized clinical trial (GUARDIAN) of 11,590 patients with unstable angina and non-ST-segment elevation myocardial infarction undergoing either angioplasty or surgical revascularization, NHE inhibition with cariporide failed to reduce the incidence of myocardial infarction and death.²⁷⁷ However, in a subgroup analysis of patients undergoing coronary artery bypass, there was a decrease in rates of myocardial infarction or death 6 months postoperatively, provoking another trial (EXPEDITION) limited only to patients undergoing surgical revascularization, which demonstrated a decrease in myocardial infarction rate accompanied by an increase in the incidence of stroke.²⁷⁸

MOLECULAR MANIPULATION

During the normal temporal development of the myocardium, there is the phenotypic induction, expression, and synthesis of a defined number of genes. Under pathophysiologic conditions including stress, disease, and induction resulting from intrinsic or extrinsic insult, there is an adaptive remodulation of gene synthesis that is often not initially apparent at the gross anatomic or histologic level. Recent advances in molecular, cellular, and genetically based technologies have allowed these events and altered genes and gene products to be identified, which may aid in the development of new therapeutic interventions.²⁷⁹

Response to Changes in a Patient's Condition

Medication Safety and Reconciliation

Active Involvement of Patients in Their Own Care

Communication among Caregivers

MEASUREMENT OF CARE

CONCLUSION

At the turn of the 20th century, Dr. Ernest A. Codman (1869-1940) was rejected by the Boston medical community for his maverick ideas supporting the evaluation and publication of surgical outcomes. Codman eventually founded his own hospital dedicated to the study of “end results” and published his outcomes.¹ His work was seminal in the establishment of the American College of Surgeons and the Joint Commission. A half-century later, the Boston medical community redeemed itself with the landmark report by Beecher and Todd, “A Study of the Deaths Associated with Anesthesia and Surgery.”² Death was the designated outcome under study, as it was the one that could be agreed on by all investigators.³ Two decades later, the focus shifted to the application of the critical incident technique and identification of remediable factors that contribute to anesthesia-related morbidity and mortality, and the eventual creation of the Anesthesia Patient Safety Foundation.⁴⁻⁶

In the spirit of Codman’s focus on end results and the Anesthesia Patient Safety Foundation’s focus on remediation, cardiac surgeons have played a major role in the study of outcomes and the implementation of quality improvement techniques. The relative uniformity and limited types of cardiac operations, together with their case volume, aggregate cost, and high public profile, impelled interested stakeholders to quantify outcomes. In 1972, the Department of Veterans Affairs (VA) created a Cardiac Surgery Consultants Committee Advisory Group, which resulted in the first multi-institutional

cardiac surgery outcomes database. Until 1988, the main outcomes were volume and unadjusted mortality.⁷ In 1987, the Health Care Financing Administration (HCFA) published raw institution-specific mortality rates for Medicare patients.⁸ Mortality rates were generated for entire hospitals in aggregate, as well as for specific diagnosis-related groups (DRGs), including coronary artery bypass graft (CABG). With growing concern over the confusion developing from raw mortality rates, the VA introduced a risk-adjustment model and created what is now known as the VA Continuous Improvement in Cardiac Surgery Program.⁹ Motivated by both clinical and statistical imperatives, in 1989 the Society of Thoracic Surgeons (STS) developed its own voluntary, risk-adjusted database for cardiac surgery. Also in 1989, Parsonnet and colleagues pioneered a predictive model that classified patients into five groups of increasing operative risk according to 14 preoperative risk factors.¹⁰ The model proved to be highly predictive when applied to a large number of patients in three hospitals. In the 1990s various statistical methods were developed to adjust for preoperative risk hazard as well as social and geographic differences.^{11,12} In 1987 in New England, a consortium of hospitals, the Northern New England Cardiovascular Disease Study Group, began to collect data uniformly in a common registry.¹³ The Alabama Coronary Artery Bypass Grafting Cooperative project gathered data beginning in 1995.¹⁴ However, among these and other registries established in the early and mid-1990s, the

universal finding was that operative mortality varied widely among institutions, even after risk adjustment.¹⁴⁻¹⁶ This observation presaged complementary movements: (1) public reporting of statewide outcomes and (2) strategic interventions to improve outcomes. Hannan and coworkers' studies of CABG mortality in New York State led to the first statewide reporting of operative mortality.^{17,18} Statutory requirement for public reporting was subsequently adopted in Pennsylvania, New Jersey, and Massachusetts.¹⁹⁻²¹

An equally important result has been the cooperative analysis of outcomes with a focus on performance improvement. The Northern New England Cardiovascular Disease Study Group became a leader in this movement, in which surgeons, cardiologists, anesthesiologists, nurses, and perfusionists collaborated to review data and current practice, target key variables that drive outcomes, and organize improvement projects, such as inter-institutional site visits and study protocols, with resultant decline in CABG mortality rates.¹⁵ A number of regional, national, and even international groups have followed this registry and quality improvement model, establishing benchmarks for the cardiac surgical "industry."²²⁻²⁴

Around the turn of the 21st century, national specialty societies began establishing guidelines for the application of interventional and surgical technologies. The American College of Cardiology (ACC) and American Heart Association (AHA) published their first *Guidelines for Coronary Bypass Surgery* in 1999, with updates in 2004 and 2011.^{25,26,26a} These include class I, useful and effective; class IIa, evidence favors usefulness; class IIb, evidence less well established; class III, not useful or effective and, in some cases, harmful. Similar guidelines have been established for valvular surgery.^{27,28}

The net impact of all these activities is dramatically apparent when viewing the decline in the ratio of observed (O) to expected (E) CABG mortality of patients, as measured by the STS database (Fig. 66-1).²⁹

FIGURE 66-1 ■ Observed-to-expected mortality ratio for all isolated coronary artery bypass graft patients from 2000 to 2005. Graph shows the results of logistic modeling for patient risk. The decline over the 5 years is statistically significant ($P < 0.0001$) for the trend (2000-2005). (From Grover FL: The bright future of cardiothoracic surgery. *Ann Thorac Surg* 85:8-24, 2008.)

NATIONAL LANDSCAPE FOR QUALITY AND SAFETY

In addition to quality and safety initiatives specific to cardiac surgery, a major cultural change has occurred in the United States during the early 21st century. Leadership in the prioritization of quality and safety has come from the Institute of Medicine (IOM). In a groundbreaking publication in 1999, "To Err Is Human," the IOM made several important contributions.³⁰ First, the report estimated that up to 98,000 patients each year die as a result of medical error. They identified that errors are often caused by faulty systems, processes, and conditions. They cited the work of Lucian Leape and colleagues, who codified four types of errors: diagnostic, treatment, preventive, and other (Box 66-1).³¹

To achieve a better safety record, the IOM report recommended a four-tiered approach:

1. Establishing a national focus to create leadership, research, tools, and protocols to enhance the knowledge base about safety
2. Identifying and learning from errors by developing a nationwide public mandatory reporting system and by encouraging health care organizations and practitioners to develop and participate in voluntary reporting systems
3. Raising performance standards and expectations of improvements in safety through the actions of oversight organizations, professional groups, and group purchasers of health care
4. Implementing safety systems in health care organizations to ensure safe practices at the delivery level (i.e., a culture of safety)

BOX 66-1 Types of Medical Errors

DIAGNOSTIC

- Error or delay in diagnosis
- Failure to use indicated tests
- Use of outmoded tests or therapy
- Failure to act on results of monitoring or testing

TREATMENT

- Error in the performance of an operation, procedure, or test
- Error in administering the treatment
- Error in the dosage or method of using a drug
- Avoidable delay in treatment or in responding to an abnormal test
- Inappropriate (not indicated) care

PREVENTIVE

- Failure to provide prophylactic treatment
- Inadequate monitoring or follow-up of treatment

OTHER

- Failure of communication
- Equipment failure
- Other system failure

Adapted from Leape L, Larwthers AG, Brennan TA, et al: Preventing medical injury. Qual Rev Bull 19:144-149, 1993.

Two years later, the IOM published another landmark report, “Crossing the Quality Chasm,”³² which set a national agenda aimed at narrowing differences in quality among providers of medical care. Instead of focusing attention on a single outcome, the IOM focused on the quality of the entire patient experience, defining it in six key dimensions as being “safe, effective, efficient, timely, patient-centered, and equitable.” The model promulgated a balanced approach to assessment of quality, incorporating clinical outcomes with patient experience and the appropriate allocation of resources. Furthermore, the report identified key redesign imperatives for care delivery:

- Reengineered care processes
- Effective use of information technologies
- Knowledge and skills management
- Development of effective teams
- Coordination of care across patients—conditions, services, sites of care—over time

One other key focus of this IOM report addresses patient engagement:

- Care is based on continuous healing relationships.
- Care is customized according to patient needs and values.
- Patient is the source of control.
- Knowledge is shared and information flows freely.
- Transparency is necessary.
- Needs are anticipated.

These two IOM reports raised the bar to a new level of excellence that transcended the expertise of a single care provider. In 2006, a third IOM report, “Performance Measurement: Accelerating Improvement,” laid the groundwork for performance measurement.³³ Achieving excellence now required a careful orchestration of care delivery, incorporating evidence-based care processes, as well as coordinated care infrastructure across the care delivery continuum—both inpatient and outpatient. Hardwiring for excellence became a priority, leading the Joint Commission (formerly known as JCAHO) to begin requiring demonstration of evidence-based and safe practices in the delivery of care. Payers and purchasers followed suit. The Centers for Medicare and Medicaid Services (CMS) instituted the requirement for submission of “core measures,” evidence-based practices in the care of patients with acute myocardial infarction, heart failure, pneumonia, and selected surgeries (including cardiac surgery).

Another key player has been the National Quality Forum (NQF), a public-private partnership created to develop and implement a national strategy for health care quality measurement and reporting. NQF member organizations have worked together to promote a common approach to measuring health care quality and fostering system-wide capacity for quality improvement. Yet another influence has come from the Leapfrog Group, an association of private and public sector group purchasers, who have created a market-based strategy to improve safety and quality. Their public ranking includes recognition for the use of computerized provider order entry, evidence-based hospital referrals, and the staffing of intensive care units with physicians credentialed in critical care medicine. In addition, they generate an aggregate

Safety Score (A through F) for each hospital based on these data.

An outcome of these various national initiatives is the standardization of surgical care. Postoperative complications have a significant impact on mortality, length of stay (3 to 11 days), and cost.³⁴ In a study of Medicare beneficiaries in 2009, surgical patients had a 30-day readmission rate of 12.7%.³⁵ To decrease readmissions, CMS began reporting 30-day readmission rates for certain diagnoses in 2009. In October 2012, CMS began a pay-for-performance program in which hospitals with excessive readmissions for particular reportable medical diagnoses are penalized. The goal of the pay-for-performance program set forth by CMS and the secretary of Health and Human Services was to reduce readmissions by 20% by the end of 2013, and 18.5% reduction was achieved in 2012.

In 2002, CMS, in collaboration with the Centers for Disease Control and Prevention, implemented the National Surgical Infection Prevention Project with the goal of decreasing the morbidity and mortality rates associated with postoperative surgical site infections by promoting appropriate selection and timing of prophylactic antimicrobials.³⁶ In April 2003, this group joined with representatives of the VA, American College of Surgeons, American Society of Anesthesiologists, Agency for Healthcare Research and Quality, American Hospital Association, and Institute for Healthcare Improvement to align efforts to reduce surgical complications and mortality. This collaboration resulted in the development of the Surgical Care Improvement Project (SCIP), a national quality partnership of organizations committed to improving the safety of surgical care through the reduction of postoperative complications.³⁶ The rapid rate of adoption of the SCIP measures can be tracked on the CMS website Hospital Compare (www.hospitalcompare.hhs.gov), showing rates of compliance with these measures in hospitals across the country.

EVOLVING LANDSCAPE OF QUALITY AND SAFETY IN CARDIAC SURGERY

From 1989 to 2007, the STS database grew to become the largest and most comprehensive single-specialty clinical database in health care in the world.³⁷ In view of the increasing interest of payers and regulators to compare cardiac surgery quality, the STS established a Quality Measurement Task Force (QMTF). The task force’s goal was to develop a methodology for comprehensive assessment of adult cardiac surgery quality of care. The assessment was to include both individual measures and a composite quality score. Guiding principles included the following³⁸:

- Quality assessment should be at the level of the program or hospital, rather than the individual surgeon.
- Initial quality reports should focus on CABG surgery.
- Quality measures should be chosen from among those endorsed by the National Quality Forum.
- Quality measure selection should be consistent with the principles and criteria recommended in

BOX 66-2 Society of Thoracic Surgeons Quality Measures**PERIOPERATIVE MEDICAL CARE**

- Preoperative beta blockade
- Discharge antiplatelet therapy
- Discharge beta blockade
- Discharge antilipid therapy
- Antibiotic prophylaxis duration and selection

OPERATIVE CARE

- Use of at least one internal mammary artery

OPERATIVE MORTALITY RISK-ADJUSTED**POSTOPERATIVE MORBIDITY: ABSENCE OF ANY SERIOUS COMPLICATION**

- Renal failure
- Deep sternal wound infection
- Reexploration for any cause
- Stroke
- Prolonged ventilation/intubation

Adapted from Shabian DM, Edwards FH, Ferraris VA, et al: Quality measurement in adult cardiac surgery. Part 1: Conceptual framework and measure selection. Ann Thorac Surg 83(Suppl):S3–12, 2007.

the 2006 IOM report “Performance Measurement: Accelerating Improvement.”

- Quality measures should be available as data elements in the STS National Adult Cardiac Surgery Database.
- Quality scores should take into account structure, process, and outcomes.
- Quality scores should assess three temporal domains—preoperative, operative, and postoperative.
- Quality scores should satisfy multiple criteria for validity.
- Quality scores should be interpretable and actionable by providers.

In 2007, the STS QMTF created 11 measures within four domains: perioperative medical care, intraoperative care, risk-adjusted operative mortality, and postoperative morbidity.³⁹ Statistical analysis was based on actual 2004 STS data, representing 133,149 coronary artery bypass procedures.³⁸ The STS QMTF measures are listed in [Box 66-2](#).

CARDIAC SURGERY TEAMWORK AND COMMUNICATION

Defining best practice through quality and safety measures has been a major accomplishment. Implementing these measures has proved to be a challenge because it has required a reengineering of workflow and, in some cases, a redesigning of care delivery. Successful implementation of best practices depends on teamwork across medical specialties and across disciplines, as well as with the patients and their families. The interventions that can contribute to the quality and safety of care delivered to cardiac surgery patients follow. Central to the effective care of cardiac surgical patients is effective teamwork.

The critical elements of teamwork include the 6 “Cs”: communication, cooperation, coordination, cognition (shared understanding of patient care goals), conflict resolution, and coaching (team training).⁴⁰ In a review of malpractice litigation, 87% of system failures were a result of communication breakdown, primarily between caregivers.⁴¹ The Joint Commission reported that communication failures were the leading root cause of 65% of sentinel events between 2004 and 2012.⁴²

Breakdown in communication and surgery workflow is exceedingly common. In one study of intraoperative communication failures during complex operations, communication failures occurred in every case at a rate of one every 8 minutes.⁴³ In another study of disruptions in a cardiac surgical operating room, breakdown in teamwork and communication occurred at a rate of 11 per case.⁴⁴ Although some of these disruptions can seem innocuous and do not seem to affect patient outcome, minor events during cardiac surgery can accumulate and impair the team’s ability to recover from major events and are significantly associated with death and near misses.⁴⁵ Catchpole and colleagues reported that for every 3 minor problems above the mean of 9.9 per case, intraoperative performance was hindered, and operative time increased.⁴⁶ Thus nontechnical skills in the operating room such as teamwork and communication have been shown to negatively impact patient outcomes.

Measurement tools have emerged to assess nontechnical skills such as communication and teamwork dynamics. The Oxford Non-Technical Skills (NOTECHS) is a teamwork assessment tool that was adapted from the aviation industry and measures skills in four categories: problem solving/decision making, situational awareness, leadership/management, and cooperation/teamwork. The Observational Teamwork Assessment for Surgery (OTAS) is another teamwork assessment tool that uses a procedural task checklist centered on patient, equipment, and communication task ratings. Both the NOTECHS and the OTAS have been validated and found to be reliable in measuring nontechnical skills in the operating room.^{47,48} The purpose of using these measurement tools is to test the efficacy of proposed interventions to improve nontechnical skills before implementation.

Teamwork dynamics has been extensively studied in the aviation industry after several aviation accidents were attributed to teamwork failure. In an effort to improve communication and effective teamwork, the aviation industry developed crew resource management (CRM), which is a training protocol designed for high-stress, high-stakes situations where human error can result in devastating consequences. CRM training aims to foster team empowerment and a safety culture in which any team member can raise concerns and respectfully question authority if he or she believes that an error is occurring. Training in CRM focuses on communications, situational awareness, problem solving, leadership, decision making, and adaptability in order to promote safety and optimize team efficiency. Given the proven efficacy of CRM, medicine has followed suit in implementing an adapted version of CRM in critical areas of medicine and surgery. In a study using CRM-style teamwork training in general and vascular surgery, Oxford researchers

reported that NOTECHS teamwork scores significantly improved and procedural error rates were reduced.^{48,49} In a national prospective teamwork training study, the VA's medical team training program demonstrated that CRM-based team training significantly reduced annual mortality by 18%, reduced the incidence of wrong-site surgery, and improved compliance with best practices.⁵⁰⁻⁵³ This study also demonstrated that there is a dose-response relationship between team training duration and mortality: for every 3 months of team training, there was a reduction of 0.5 deaths per 1000 operations.⁵⁰

One other key area in communication and teamwork, as articulated by the IOM, is the active engagement of the patient. Providing the patient with the information he or she needs, engaging the patient in the plan, and sharing decision making while respecting the patient as the ultimate decision maker yields benefits for caregivers as well as patients and ensures alignment of goals and supports patient participation in the recovery process.

PERIOPERATIVE CARE

Preprocedure Verification, Marking, Time-Out, and Briefing

Much has been written about the importance of the Universal Protocol for Preventing Wrong Site, Wrong Procedure, and Wrong Person Surgery, and few would dispute the value of this preprocedure checking.⁵⁴⁻⁵⁷ Time-outs, checklists, and briefings have been shown to reduce errors in communication and improve teamwork. Although a major focus was initially on operating room (OR) procedures, the Universal Protocol applies to most other procedures that involve puncture or incision of the skin, or insertion of an instrument or foreign material into the body—for example, peripherally inserted central catheter lines, percutaneous aspirations, biopsies, cardiac and vascular catheterizations, and endoscopies. Growing experience has demonstrated the value of hardwiring the Universal Protocol with specific rules and clear accountability. Workflow must be reengineered to ensure the availability of critical parties. Introduction of stopgap measures are helpful (e.g., the blade is not put on the scalpel until the time-out is completed). Whereas checklists are structured and closed-ended and involve reading aloud and verifying specific information, briefings are open-ended and involve a dialogue to confirm procedure details, identify problems, exchange information, and ask questions. In a study of 35,000 cases, briefings have been shown to shorten the duration of surgical procedures by reducing interruptions and distractions and only take 2.9 minutes on average (range 1 to 5 minutes).⁵⁸⁻⁶⁰ Although studies have demonstrated that briefings can reduce intraoperative distractions and improve workflow, to date, it is not universally implemented because of individual and institutional resistance to routine briefings.

Antibiotic Administration

The goal of antibiotic prophylaxis is to use an agent that is safe and cost-effective and that has a spectrum of action

that covers most of the probable intraoperative organisms.^{61,62} Antibiotic administration must be completed before incision and should not be given more than 1 hour before incision (except for vancomycin, which can be given 2 hours before incision). Antibiotic selection should align with evidence-based recommendations. There should be coordination between anesthesiologist and surgeon. Communication from surgeon to anesthesiologist about antibiotic selection is most effective when it occurs in a standardized fashion. Reasons for exceptions to standard antibiotic protocol need to be documented and communicated. Pharmacy staff also need to be in the communication loop to ensure that drug preparations are available for timely infusion and completion before surgery. Postoperative orders need to be clear about the number of postoperative antibiotic doses due and by what time the last dose should be completed to stay within the 48-hour postoperative window. Although there is some evidence that single-dose prophylaxis or 24-hour prophylaxis may be as effective as 48-hour prophylaxis, the STS published a practice guideline recommending 48 hours of prophylaxis, because few studies have directly compared 24 hours of prophylaxis with 48 hours of prophylaxis.⁶³ In a meta-analysis comparing short-term perioperative antibiotic prophylaxis (<24 h) compared to longer term antibiotic prophylaxis (>24 h), patients receiving antibiotics for more than 24 hours had a 38% decreased risk in developing sternal surgical site infection.⁶⁴ However, prophylaxis should be concluded at 48 hours, because administration for longer periods has been associated with an increased risk of infection with drug-resistant organisms.⁶⁵

Preoperative Beta Blockade

An observational analysis of 629,877 patients undergoing CABG between 1996 and 1999 demonstrated that preoperative beta blocker therapy was associated with a small but consistent survival benefit, except among patients with a left ventricular ejection fraction of less than 30%.⁶⁶ Furthermore, many studies have demonstrated the benefit of preoperative beta blockers in reducing the incidence of postoperative atrial fibrillation.⁶⁷ Atrial fibrillation occurs in up to one third of patients after open heart surgery. In an analysis of 52 published studies representing almost 10,000 patients undergoing open heart surgery, supraventricular tachycardias, including atrial fibrillation, occurred in 29% of patients who did not receive prophylactic drugs and in 19% of patients given beta blockers.⁶⁷

Postoperative Glucose Control

Glucose control through continuous infusion of insulin has been shown to reduce mortality and surgical site infections in both diabetic and nondiabetic patients.⁶⁸⁻⁷¹ Intraoperatively, several factors contribute to hyperglycemia, including cardiopulmonary bypass (CPB) pump prime fluid composition, temperature while on CPB, and medications such as catecholamines and glucocorticoids.⁷² The current measure of glucose control is based on the value identified at 6 AM postoperatively, with a

goal of less than or equal to 200 mg/dL. During the first 24 postoperative hours, glucose control is best achieved through intravenous insulin titrated on a sliding scale, based on fingerstick glucose levels measured every 1 to 2 hours, and this requires effective nursing leadership. Although previous studies advocated aggressive glycemic control (blood glucose 90 to 120 mg/dL) in patients undergoing cardiac surgery, this has been associated with increased incidence of hypoglycemic events. As a result, it is now recommended that diabetic cardiac surgical patients have a blood glucose maintained between 120 and 180 mg/dL.^{73,74} Protocols should incorporate mechanisms to recognize when the patient's endogenous glucose regulation begins to normalize, so as to avoid hypoglycemia. Full implementation of these interventions requires careful orchestration of critical care staff members, including nursing, respiratory therapy, midlevel practitioners, and physicians, with clear designation of accountability for tracking and reporting.

POSTOPERATIVE MORBIDITY

Ventilator-Associated Pneumonia

Most cardiac surgery patients are extubated within a day of surgery. However, for those who remain intubated for longer, meticulous attention to prevention of ventilator-associated pneumonia (VAP) is critical. VAP is an airway infection that develops more than 48 hours after intubation. Ventilated patients with VAP have a mortality rate of 46% as compared with 32% for ventilated patients without VAP.⁷⁵ On the basis of a growing body of literature, the Institute for Health Care Improvement identified four best practices that can decrease the incidence of VAP: (1) elevation of the head of the bed, (2) daily "sedation vacations" and assessment of readiness to extubate, (3) peptic ulcer disease prophylaxis, and (4) deep venous thrombosis prophylaxis.^{76,77}

Central Line Infections

Central line infections are another source of morbidity and mortality, with mortality estimates ranging from 4% to 20%.⁷⁸ The Institute for Health Care Improvement recommends five key interventions to decrease central line infections: (1) hand hygiene; (2) maximal barrier precautions on insertion; (3) chlorhexidine skin antisepsis; (4) optimal catheter site selection, with subclavian vein as the preferred site for nontunneled catheters; and (5) daily review of line necessity, with prompt removal of unnecessary lines. As with VAP, reduction in the incidence of central line infection is a shared responsibility among critical care staff.^{79,80}

Deep Sternal Wound Infections

Deep sternal wound infections are estimated to occur in 1% to 3% of cardiac surgery patients; they result in an in-hospital mortality rate of up to 20% and, in some studies, an increase in the long-term mortality rate as well.^{81,82} Risk factors include obesity, malnutrition,

diabetes mellitus, smoking, preoperative hemodynamic instability, preoperative renal failure on dialysis, use of bilateral internal thoracic arteries, and sepsis or endocarditis after CABG.⁸¹⁻⁸⁴ *Staphylococcus aureus* is a common pathogen.⁸⁵ Infection-reduction strategies include glucose control for diabetic as well as nondiabetic patients, reduction of colonization through a chlorhexidine scrub the night before surgery, mupirocin to the nares preoperatively and postoperatively, appropriate antibiotic selection, optimal administration time and duration, and the minimizing of traffic in and out of the OR during surgery.^{69,82-84} Surgical interventions include standardized preparation and draping, hair clipping instead of shaving, and meticulous wound closure.^{82-84,86}

Postoperatively, there is evidence for the benefit of sports-bra support for large-breasted patients.⁸⁴ Deep sternal wound infection (mediastinitis) is viewed as a preventable condition by CMS. Therefore, patients who develop a deep sternal wound infection during the admission for cardiac surgery no longer receive the incremental payment for this condition.

Response to Changes in a Patient's Condition

Most patients who experience a cardiac arrest in the hospital demonstrate identifiable signs of deterioration before the arrest. The most common signs are abnormal vital signs and hypoxia.⁸⁷⁻⁸⁹ A rapid response team (RRT) is a group of clinicians who deliver emergency care to a patient at the bedside. The RRT does not replace the patient's care team but ensures that immediate assistance is available when there is a sudden deterioration. The RRT may include the critical care nurse or physician as well as a respiratory therapist. The RRT may be called at any time by anyone in the hospital to assist in the care of a patient who appears acutely ill, so as to avoid cardiac arrest or other adverse event. Facilities that have implemented RRTs have reported a reduction in the number of cardiac arrests and deaths, as well as a reduction in intensive care unit and hospital length of stay among survivors of cardiac arrest.⁸⁹ On surgical services, implementation of RRTs has been associated with a reduction in the incidence of respiratory failure, stroke, severe sepsis, acute renal failure, and postoperative mortality.⁹⁰

Medication Safety and Reconciliation

The IOM estimated that medication errors have accounted for 7000 deaths each year.³⁰ Injuries attributable to the use of medications are designated as adverse drug events (ADEs). Hospitalized patients who experience an ADE have a mortality rate that is almost twice that of patients without an ADE.⁹¹ Prevention of ADEs has been designated a national priority.⁹² The Joint Commission has identified four categories of high-risk medications: anticoagulants, insulin, sedatives, and opioids. Most cardiac surgery patients receive most or all of these types of medications. Attention to administration is critical during the hospital stay, during transfers in and out of critical care or recovery units, and at discharge.

Anticoagulation errors can be reduced with the implementation of standardized protocols for initiation and dosage adjustment of coumadin and heparin. Anticoagulation protocols should specify target laboratory values and frequency of monitoring, as well as designated accountability for dose adjustments. Insulin administration protocols should also specify target glucose values and frequency of monitoring. Protocols for administration of intravenous insulin infusion outside a critical care setting should address nursing staff ratios to ensure timely and frequent glucose monitoring. Sedation and opioid protocols should address the management of sleep apnea, identifying high-risk patients in advance of surgery.⁹³ Timely pain assessment and control is critical for the patient's experience and recovery. Use of an objective pain scale can assist in monitoring, ensuring that the targets afford patient comfort without jeopardizing respiratory status. For example, a pain level of 0 may be a sign of overmedication and thus a risk for respiratory depression.

Of all medication errors, 46% occur at transition points (e.g., admission to hospital, transfer between units, discharge from hospital).⁹⁴ Medication reconciliation across the continuum of care ensures that patients receive all intended medications and no unintended medications after transitions in care locations. The Joint Commission has defined medication reconciliation as the process of comparing a patient's medication orders to all of the medications that the patient has been taking. The purpose is to avoid medication errors such as omissions, duplications, dosing errors, or drug interactions. Medication reconciliation should be performed at every transition of care in which new medications are ordered or existing orders are rewritten. The process has five steps: (1) develop a list of current medications, (2) develop a list of medications to be prescribed, (3) compare the medications on the two lists, (4) make clinical decisions based on the comparison, and (5) communicate the new list to appropriate caregivers and to the patient. Medication reconciliation has been shown to significantly decrease medication errors.⁹⁴

Active Involvement of Patients in Their Own Care

Patient activation has been shown to be a critical factor in improving outcomes and influencing costs.⁹⁵ Patients and their families play an active role in the medication reconciliation process. They should review all medications and understand both generic and proprietary names. For cardiac surgery patients being discharged on coumadin, the patient and family should receive instructions on how to take the medication, the foods and medications that can affect coumadin effectiveness, and how to recognize and what to do for signs and symptoms of bleeding. The clinician responsible for monitoring and dose adjustments should be clearly designated and an appointment for the post-discharge blood level monitoring made.

Communication among Caregivers

Transitions across units and in and out of the hospital are periods of risk. Standardized handoffs by clinical

staff are a way of ensuring that each caregiver has complete information. There must be timely and complete communication with the primary care physician who will be caring for the patient after discharge.

MEASUREMENT OF CARE

The IOM has provided clinicians with a clear roadmap for improvement, focusing on safety and quality and the assessment of outcomes and patient experience. Regular and frequent measurement is essential to achieving and maintaining excellence. The NQF is a nonprofit organization that operates under a three-part mission to improve the quality of American health care by:

- Building consensus on national priorities and goals for performance improvement and working in partnership to achieve them;
- Endorsing national consensus standards for measuring and publicly reporting on performance; and
- Promoting the attainment of national goals through education and outreach programs.

NQF measures ensure standardization and validation and are used by STS and by CMS for the Hospital Inpatient Quality Reporting Program (IQR), including SCIP (Table 66-1). Participation in national and state databases affords the opportunity to compare performance with that achieved in benchmark institutions. However, as these reports may lag by many months, performance must also be tracked in real time for early detection of variances. In addition to manual data abstraction, some vendors and payers may calculate and publicize morbidity and mortality rates based on proprietary risk-adjustment models derived from International Statistical Classification of Diseases and Related Health Problems (ICD)-9 codes. ICD-9 codes are assigned by coders at the time of discharge and are based on documentation in the chart from physicians, nurse practitioners, and physician assistants. The precision of the documentation has an impact on the level of detail of the ICD-9 codes assigned. Complete capture of all relevant ICD-9 codes ensures that risk-adjustment models accurately depict a patient's risk. Notable is the fact that coders cannot code from laboratory results, only from the notes of a physician or mid-level practitioner. For example, a patient who has a creatinine of 2.5 is not assigned a diagnosis of renal failure or renal insufficiency unless those words appear in the documentation. Furthermore, clinicians should review terminology definitions. *Renal failure* is major comorbidity or complication reflecting an acute rise in creatinine from baseline. *Renal insufficiency*, in contrast, is a chronic steady-state condition and does not contribute to the coded risk profile. In October 2014, ICD-9 codes ($N = 14,000$) will be retired and replaced with ICD-10 ($N = 69,000$), which requires greater specificity in documentation in some areas.

Finally, a great advance in the measurement of care is the availability of the patient's own assessment of the care delivered. In 2006, CMS introduced the Hospital Consumer Assessment of Healthcare Providers and Systems (HCAHPS) survey. The survey is administered, usually by mail, to a statistically significant subset of discharged

TABLE 66-1 National Quality Forum (NQF) Measures

Measure	NQF Status	Description
STS CABG Composite Score	NQF #0696 endorsed	This multidimensional performance measure assesses surgical performance based on a combination of 11 NQF-endorsed CABG process and outcomes measures, grouped into four domains: 1. Perioperative medication domain, scored all-or-none and consisting of: 0127—Preoperative beta blockade 0117—Beta blockade at discharge 0116—Antiplatelet medication at discharge 0118—Antilipid treatment at discharge 2. Operative care process domain 0134—Use of an internal mammary artery in CABG 3. Risk-adjusted operative mortality 0119—Risk-adjusted operative mortality for CABG 4. Risk-adjusted morbidity, scored any-or-none and consisting of: 0131—Stroke/cerebrovascular accident 0115—Surgical reexploration 0130—Deep sternal wound infection rate 0114—Postoperative renal failure 0129—Prolonged intubation (ventilation) Participants receive a score for each of the four domains, plus an overall composite score. The overall composite score was created by “rolling up” the four domain scores into a single number. In addition to receiving a numeric score, participants were assigned to rating categories designated as one (below average performance), two (average performance), or three (above average performance) stars.
Outcome Measures		
Risk-Adjusted Deep Sternal Wound Infection Rate	NQF #0130	Percentage of patients aged 18 years and older undergoing isolated CABG who, within 30 days postoperatively, develop deep sternal wound infection involving muscle, bone, and/or mediastinum requiring operative intervention
Risk-Adjusted Operative Mortality for Aortic Valve Replacement (AVR)	NQF #0120	Percentage of patients undergoing AVR who die, including both (1) all deaths occurring during the hospitalization in which the procedure was performed, even if after 30 days, and (2) those deaths occurring after discharge from the hospital, but within 30 days of the procedure
Risk-Adjusted Operative Mortality for AVR + CABG Surgery	NQF #0123	Percentage of patients undergoing combined AVR and CABG who die, including both (1) all deaths occurring during the hospitalization in which the procedure was performed, even if after 30 days, and (2) those deaths occurring after discharge from the hospital, but within 30 days of the procedure
Risk-Adjusted Operative Mortality for CABG	NQF #0119	Percentage of patients aged 18 years and older undergoing isolated CABG who die, including both (1) all deaths occurring during the hospitalization in which the CABG was performed, even if after 30 days, and (2) those deaths occurring after discharge from the hospital, but within 30 days of the procedure
Risk-Adjusted Operative Mortality for Mitral Valve (MV) Repair	NQF #1501	Percentage of patients undergoing MV repair who die, including both (1) all deaths occurring during the hospitalization in which the procedure was performed, even if after 30 days, and (2) those deaths occurring after discharge from the hospital, but within 30 days of the procedure
Risk-Adjusted Operative Mortality for MV Repair + CABG Surgery	NQF #1502	Percentage of patients undergoing combined MV repair and CABG who die, including both (1) all deaths occurring during the hospitalization in which the procedure was performed, even if after 30 days, and (2) those deaths occurring after discharge from the hospital, but within 30 days of the procedure
Risk-Adjusted Operative Mortality for Mitral Valve (MV) Replacement	NQF #0121	Percentage of patients undergoing MV replacement who die, including both (1) all deaths occurring during the hospitalization in which the procedure was performed, even if after 30 days, and (2) those deaths occurring after discharge from the hospital, but within 30 days of the procedure
Risk-Adjusted Operative Mortality for MV Replacement + CABG Surgery	NQF #0122	Percentage of patients undergoing combined MV replacement and CABG who die, including both (1) all deaths occurring during the hospitalization in which the procedure was performed, even if after 30 days, and (2) those deaths occurring after discharge from the hospital, but within 30 days of the procedure
Risk-Adjusted Postoperative Renal Failure	NQF #0114	Percentage of patients aged 18 years and older undergoing isolated CABG (without preexisting renal failure) who develop postoperative renal failure or require dialysis

TABLE 66-1 National Quality Forum (NQF) Measures—cont'd

Measure	NQF Status	Description
Risk-Adjusted Prolonged Intubation (Ventilation)	NQF #0129	Percentage of patients aged 18 years and older undergoing isolated CABG who require intubation for more than 24 hours
Risk-Adjusted Stroke/Cerebrovascular Accident	NQF #0131	Percentage of patients aged 18 years and older undergoing isolated CABG who have a postoperative stroke (i.e., any confirmed neurologic deficit of abrupt onset caused by a disturbance in blood supply to the brain) that did not resolve within 24 hours
Risk-Adjusted Surgical Reexploration	NQF #0115	Percentage of patients aged 18 years and older undergoing isolated CABG who require a return to the operating room for bleeding with or without tamponade, graft occlusion, valve dysfunction, or other cardiac reason
Process Measures		
Antilipid Treatment at Discharge	NQF #0118	Percentage of patients aged 18 years and older undergoing isolated CABG who were discharged on a statin or other lipid-lowering regimen
Antiplatelet Medication at Discharge	NQF #0116	Percentage of patients aged 18 years and older undergoing isolated CABG who were discharged on antiplatelet medication
Use of IMA in CABG	NQF #0134	Percentage of patients aged 18 years and older undergoing isolated CABG who received an IMA graft
Preoperative Beta Blockade (CMS SCIP Card-2)	NQF #0127	Percentage of patients aged 18 years and older undergoing isolated CABG who received beta blockers within 24 hours preceding surgery
Beta Blockade at Discharge	NQF #0117	Percentage of patients aged 18 years and older undergoing isolated CABG who were discharged on beta blockers
Prophylactic Antibiotic Received within One Hour Prior to Surgical Incision (SCIP Inf-1)	NQF #527	Percentage of patients who received prophylactic antibiotics within 1 hour prior to surgical incision
Selection of Antibiotic Prophylaxis for Cardiac Surgery Patients (CMS SCIP Inf-2)	NQF #0126	Percentage of patients aged 18 years and older undergoing cardiac surgery who received preoperative prophylactic antibiotics recommended for the operation
Duration of Antibiotic Prophylaxis for Cardiac Surgery Patients (CMS SCIP Inf-3)	NQF #0128	Percentage of patients aged 18 years and older undergoing cardiac surgery whose prophylactic antibiotics were discontinued within 48 hours after surgery end time
Cardiac Surgery Patients with Controlled Postoperative Blood Glucose (SCIP Inf-4)	NQF #300	Percentage of cardiac surgery patients with controlled 6 AM postoperative blood glucose
Urinary Catheter Removed on Postoperative Day 1 or Postoperative Day 2 (SCIP Inf-9)	NQF #453	Percentage of surgical patients with urinary catheter removed on postoperative day 1 or postoperative day 2 with the day of surgery being day zero
Venous Thromboembolism Prophylaxis (SCIP VTE-2)	NQF #218	Percentage of surgery patients who received appropriate VTE prophylaxis within 24 hours prior to anesthesia start time to 24 hours after anesthesia end time
Structure Measures		
Participation in a Systematic Database for Cardiac Surgery (CMS IQR)	NQF #0113	Participation in a clinical database with broad state, regional, or national representation that provides regular performance reports based on benchmarked data
Congenital Heart Surgery Measures		
Outcome Measures		
Operative Mortality Stratified by the Five STS-EACTS Mortality Categories	NQF # 0733	Operative mortality stratified by the five STS-EACTS mortality levels, a multi-institutional validated complexity stratification tool
Surgical Volume for Pediatric and Congenital Heart Surgery	NQF # 0732	Surgical volume for pediatric and congenital heart surgery: total programmatic volume and programmatic volume stratified by the five STS-EACTS mortality levels, a multi-institutional validated complexity stratification tool
Surgical Volume for Pediatric and Congenital Heart Surgery: Total Programmatic Volume and Programmatic Volume Stratified by the Five STS-EACTS Mortality Categories		
Participation in a National Database for Pediatric and Congenital Heart Surgery	NQF # 0734	Participation in at least one multicenter, standardized data collection and feedback program that provides benchmarking of the physician's data relative to national and regional programs and uses process and outcome measures

AVR, Aortic valve replacement; CABG, coronary artery bypass graft; CMS, Centers for Medicare and Medicaid Services; IMA, internal mammary artery; IQR, inpatient quality reporting; MVR, mitral valve replacement; NQF, National Quality Forum; SCIP, Surgical Care Improvement Project; STS-EACTS, Society of Thoracic Surgeons-European Association for Cardiothoracic Surgery; VTE, venous thromboembolism.

patients. It includes questions about the treatment of pain, the communication by physicians and nurses, and the clarity of discharge instructions. Although these are publicly reported in aggregate (with a delay of months), it is possible and important to review them close to real time and stratify by surgeon. High performance in this survey is considered vital in support of patient engagement, and sub-par performance is penalized in the CMS value-based purchasing program as well as many other pay-for-performance models.

CONCLUSION

Cardiac surgery outcomes have continued to improve over the past decade. Quality of care has increased as performance improvement initiatives have expanded. Initial focus was on the technical expertise and experience of the surgeon; this focus has expanded to include the entire care team—inside and outside the operating room—and its role in evidence-based care and harm prevention. The most recent advance is the recognition of the active involvement of patients and families in care processes and desired outcomes. The importance of the patient is underscored by the national measures of quality that include HCAHPS patient satisfaction, addressing the patient's assessment of communication and care, and ensuring that interventions by caregivers were effective for the patient, the most important person in the care delivery.

migraine and, 2050

stroke and, 2050

Pathogens

Actinobacillus actinomycetemcomitans, 1458

Actinomyces spp., 191t

Ancylostoma duodenale, 193

Aspergillus spp., 191, 221-223, 253, 256, 256f, 1750

A. flavus, 221

A. fumigatus, 221, 221f, 1458

A. niger, 221

Borrelia burgdorferi, 192

Burkholderia cepacia, 243, 255

Candida albicans, 256, 1458, 1750

Cardiobacterium hominis, 1458

Chlamydia pneumoniae, 205

Clostridium difficile, 260

Coccidioides immitis, 217-220, 220f

Eikenella corrodens, 1458

- Pathogens (*Continued*)
Escherichia coli, 1748
HACEK vs. non-HACEK groups, 1458
Haemophilus aphrophilus, 1458
Histoplasma capsulatum, 217-218, 219f, 728
Kingella kingae, 1458
Legionella spp., 205
Mycobacterium spp.
M. avium, 216, 217f
M. chelonae, 216, 216f
M. fortuitum, 216
M. intracellulare, 216
M. tuberculosis, 191-192
Mycoplasma pneumoniae, 205
Penicillium casei, 191t
Pneumocystis carinii, 253-254, 1750
Pneumocystis jiroveci, 1769-1770
Pneumocystis spp.
Pneumocystis carinii, 253-254, 1750
Pneumocystis jiroveci, 1769-1770
Pseudomonas aeruginosa, 255, 1748
Pseudomonas spp., 253
Staphylococcus aureus, 255, 467, 473, 1094, 1459, 1748
Streptococcus anginosus, 468
Strongyloides stercoralis, 193
Toxoplasma gondii, 1750, 1769
Yersinia enterocolitica, 192
- PAUs, Penetrating atheromatous ulcers (PAUs)
PA/VSD. *See* Pulmonary atresia (PA).
PCIs. *See* Percutaneous coronary interventions (PCIs).
PCR analyses. *See* Polymerase chain reaction (PCR) analyses.
PCTA. *See* Percutaneous transluminal angioplasty (PCTA).
PC trial, 965
PCV7. *See* Seven-valent pneumococcal conjugate vaccine (PCV7).
PDA. *See* Patent ductus arteriosus (PDA).
PDGF. *See* Platelet-derived growth factor (PDGF).
PDT. *See* Photodynamic therapy (PDT).
Peak end-expiratory pressure (PEEP), 244, 252
PECAM-1. *See* Platelet endothelial cell adhesion molecule (PECAM-1).
Pectoralis major muscular flaps, 1096-1097
- Pediatric congenital heart surgery
vs. adults with congenital heart disease (ACHD), 2347-2361
anatomy, segmental, 1874-1886
anesthesia, 1983-2001
anomalies
aortic root, 2198-2221
aortic valve, 2198-2221
coronary artery, 2222-2242
mitral valve, 2280-2294
pulmonary vein, 2061-2076
aorta coarctation, 2026-2042
aortopulmonary window, 2162-2179
arrhythmias, 2362-2376. *See also* Arrhythmias.
atrioventricular (AV) canal defects, 2077-2096
cardiac catheterization, 1915-1936
cardiopulmonary bypass (CPB), 1937-1965.
